When stratifying the population by serum PSA into tertiles or thirds of patients with PSA levels from 0 to 1.3, 1.4 to 3.2, and 3.3 to 10 ng/mL, three distinctly different patterns regarding symptom score and maximum flow rate changes emerge (Fig. 103-19) (Roehrborn et al, 1999a). While the initial placebo response in the lowest PSA tertile for both symptom score and flow rate was maintained over the entire 4 years of follow-up, the middle tertile experienced a slow deterioration of symptoms back to baseline and in essence the natural history and progression of disease negated any

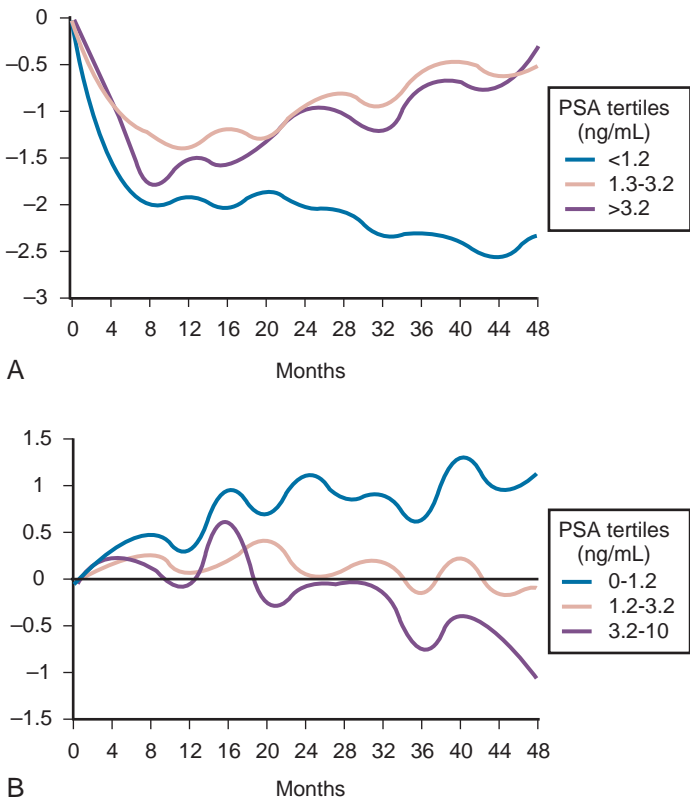

Figure 103-19. Mean changes for symptom score (A) and peak flow rate (B) in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study stratified by baseline serum prostate-specific antigen (PSA) levels. (From Roehrborn CG, Boyle P, Gould AL, et al. Serum prostate-specific antigen [PSA] is a reliable surrogate for prostate volume. *Urology* 1999;53:581-9.)

flow rate gains. In the highest PSA tertile, the symptom score increased steadily over time following an initial placebo response of -1.5 points. Over the subsequent years, the score increased by 0.5 points/yr, bringing it at the end of the study back to the original baseline level. The initial response in terms of flow rate improvement was completely negated by the progression/natural history after 2 years, and at the end of the study, this group of patients registered a net worsening of the flow rate by a mean of -1.0 mL/sec (see Fig. 103-19B). Similar results regarding the changes in symptom and maximum flow rate over time were obtained when the 150 patients for whom prostate volume measurements were available were divided into tertiles (14 to 41 mL, 42 to 57 mL, 58 to 150 mL). PLESS also periodically assessed bother due to urinary symptoms, disease-specific quality of life, aspects of sexual function, and overall sense of well-being. Surprisingly, serum PSA at baseline also predicts, after an initial placebo response, the rate of deterioration of bother, quality of life, and certain aspects of sexual function (Bruskewitz et al, 1999) (Fig. 103-20).

The Medical Therapy of Prostatic Symptoms (MTOPS) study followed 3045 men treated with either placebo, doxazosin, finasteride, or combination doxazosin-finasteride therapy for 4 to 5 years and was designed as a progression study (Bautista et al, 2003; McConnell et al, 2003). The composite end point captured either a worsening of 4 points or more on the IPSS score verified twice within 4 weeks, AUR, socially unacceptable incontinence, recurrent urinary tract infection, or renal insufficiency due to BPH (Table 103-13). The worsening of 4 points or more was chosen to reflect a clinically meaningful worsening of LUTS symptomatology. Despite an overall numerical improvement in the IPSS by -4.9 points in the placebo group (intention-to-treat cohort), about 14% of placebo-treated patients experienced a verified worsening by 4

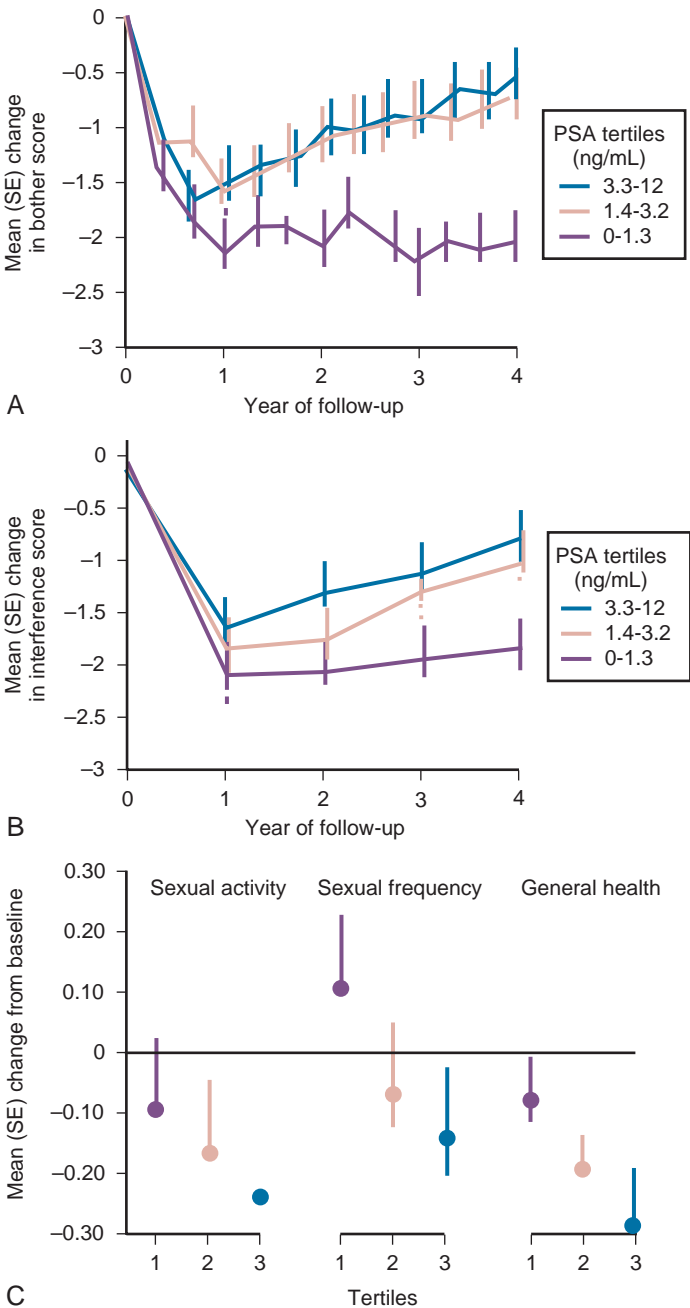

Figure 103-20. Mean changes for bother (A), for interference with activities of daily living (B), and for sexual activity, frequency, and perception of general health (C) in placebo-treated patients in Proscar Long-Term Efficacy and Safety Study stratified by baseline serum prostate-specific antigen (PSA). SE, standard error. (From Bruskewitz R, Girman CJ, Fowler J, et al. Effect of finasteride on bother and other health-related quality of life aspects associated with benign prostatic hyperplasia. PLESS Study Group. Proscar Long-term Efficacy and Safety Study. *Urology* 1999;54:670-8.)

points or more over the course of the study for an incidence of 3.6 per 100 patient-years (see Table 103-13).

PLESS and its placebo control group allowed the study of natural history and disease progression in a cohort selected for moderate symptoms and other evidence of disease (in contrast to a population-based study) on the background of the initial combined placebo responses. In MTOPS, approximately 14% of placebo-treated patients experienced a 4-point or greater worsening in the IPSS over 4 years of follow-up.

TABLE 103-13 Clinical Progression of BPH in Placebo-Treated Patients in MTOPS

EVENT	RATE OVER DURATION OF STUDY	CUMULATIVE NUMBERS OF EVENTS AT 4 YEARS	CUMULATIVE INCIDENCE (95% CI) AT 4 YEARS
Clinical progression overall	4.5	122	17 (14-20)
≥4 points IPSS increase	3.6	97	14 (11-17)
Acute urinary retention	0.6	18	2 (1-4)
Socially unacceptable incontinence	0.3	6	<1 (0-1)

Relationship between Placebo/Sham Effect and Perception of Improvement. Barry and associates (1995d) reported an important observation by assessing the relationship between changes in the AUASI and patients' global rating of improvement in over 1200 men treated in a medical treatment trial for BPH. They noted that a mean decrease in the AUASI of 3.1 points was associated with a slight improvement; however, this relationship was strictly dependent on the baseline AUASI. For patients to perceive a slight, moderate, or marked improvement, increasing drops in the AUASI were required with increasing baseline symptom severity. For patients starting with a lower versus higher baseline score, the drop had to be -7.4 versus -15.3 points, respectively, to perceive a marked improvement, -4.0 versus -8.7 for a moderate improvement, -1.9 versus -6.1 for a slight improvement, -0.2 versus -2.0 for no improvement, and +3.3 versus +1.2 for worsening to be perceived.

Longitudinal Population-Based Studies

Diokno and coworkers (1992) provided estimates of the prevalence, incidence, and remission of LUTS in 803 community-dwelling men age 60 years or older. The annual incidence of prostate surgery was 2.6% and 3.3% during years 1 and 2 of follow-up. The prevalence of at least one symptom was 35%, with annual incidence rates during years 1 and 2 of follow-up of 16.4% and 16.1%. Remission was also noted in that 22.9% of those having severe symptoms at baseline were asymptomatic at follow-up. Table 103-14 details the changes in symptom severity from one survey to the next. The tendency for fluctuation and spontaneous remission of symptoms as well as the

regression to the mean become evident from an analysis of these data.

Garraway and colleagues conducted a study of LUTS in four villages in the Forth Valley in Scotland in men 40 to 79 years old, defining BPH as a prostate volume of over 20 mL by TRUS and a maximum flow rate of less than 15 mL/sec, and applying a lower threshold to the symptom severity (Garraway et al, 1993a, 1993b; Guess et al, 1993; Tsang and Garraway, 1993). By this definition the prevalence of BPH increased at baseline from 14% in men in their 40s to 43% in men in their 60s, and about one-half of men reported interference with activities of daily living as a result of LUTS and BPH. One- and 3-year follow-up data have been reported (Lee et al, 1996). From baseline to 3 years the proportion of men with moderate symptoms increased from 34% to 45%, and significant increases in symptom level occurred for 8 of 12 symptoms queried as well as for the AUASI (increase from 6.37 to 7.88 from baseline to year 3, $P < .0001$) (Lee et al, 1996). Parallel to symptom frequency and severity, bothersomeness of symptoms increased over time (see Fig. 103-20), and the proportion of men reporting interference with two or more activities increased from 26% to 41%, with three or more activities from 18% to 27%, and with four or more activities from 15% to 18%. This study clearly demonstrated LUTS and BPH being a progressive disease, albeit with a very flat slope of progression (Fig. 103-21).

The most informative natural history study to date is the Olmsted County Study of Urinary Symptoms and Health Status among Men, which has given us much information about prevalence and severity of urinary symptoms, bother, worry and embarrassment, quality of life resulting from symptoms, and the

Figure 103-21. Changes in urinary symptoms and bothersomeness status between baseline and 3 years in a Scottish population-based study. (From Lee AJ, Russell EB, Garraway WM, et al. Three-year follow-up of a community-based cohort of men with untreated benign prostatic hyperplasia. *Eur Urol* 1996;30:11–7.)

TABLE 103-15 Change in LUTS Severity Classification: Age-Adjusted Percentage of Men and Women with LUTS Severity at Follow-up by LUTS Severity at Baseline

BASELINE (PREVALENCE)	FOLLOW-UP IN MEN				BASELINE (PREVALENCE)	FOLLOW-UP IN WOMEN			
	NONE	MILD	MODERATE	SEVERE		NONE	MILD	MODERATE	SEVERE
None (18.1)	26.8	69.9	2.8	0.5	None (13.7)	38.9	58.8	1.8	0.5
Mild (62.7)	12.2	77.0	10.3	0.5	Mild (67.4)	11.8	71.9	15.9	0.4

relationship between symptoms and other parameters such as flow rates, prostate volume, and PSA (Oesterling et al, 1993; Girman et al, 1994, 1995; Guess et al, 1995; Jacobsen et al, 2003; Sarma et al, 2003; Rule et al, 2005).

With continued follow-up of this cohort, data have emerged regarding the longitudinal changes in symptoms and flow rate over time in this population-based study. Of 904 men reporting none to mild symptoms (AUASI 0 to 7 points) at baseline, 118 reported moderate to severe symptoms (AUASI >7 points) at 18 months, and 196 at 42 months' follow-up (Jacobsen et al, 1995b). However, 47 men who had developed moderate to severe symptoms at 18 months had no to mild symptoms at 42 months. At 42 months of follow-up, an average increase in the IPSS of 0.18 (95% CI 0.13 to 0.24) points per year of follow-up was recorded. The average annual symptom score slope and variability in slope increased with patient age at baseline from a mean of 0.05 ± 1.06 (standard deviation) per year among men in their forties to 0.44 ± 1.35 per year for men in their sixties, and decreased to 0.14 ± 1.42 per year for men in their seventies (Jacobsen et al, 1996). More recently, 92 months' data showed an annual change of 0.34 points/yr, with 31% of all men reporting at least a 3-point increase. The greatest annualized increase was observed in men in their sixties with 0.6 points/yr (Rhodes et al, 2000).

The BACH survey enrolled 5502 participants ages 30 to 79 years of black, Hispanic, or white race/ethnicity (Piccolo et al, 2014). In 5-year follow-up interviews with 4144 participants, symptom progression, defined as an increase in AUASI by greater than 3 points, was reported by 21% to 33% of participants, and regression

(decrease ≥ 3) by 30% to 44% of participants, most commonly women and Hispanics. Age and higher BMI were associated with progression (*P* < .01) but not regression (Maserejian et al, 2014) (Table 103-15).

Peak flow rate measurements in a subset of about 500 men from the Olmsted County Study showed a median peak urinary flow rate slope decrease of –2.1% per year (25th percentile –4.0, 75th percentile –0.6). Peak urinary flow rate declined more rapidly with decreasing baseline rate and increasing baseline age, prostate volume, and symptom severity (all *P* = .001). When the variables were simultaneously adjusted for each other, a rapid decline (negative slope 4.5% or greater per year) was more likely in men 70 years old or older and those with a flow rate less than 10 mL/sec at baseline compared to those 40 to 49 years old and those with a flow rate of 15 mL/sec or greater, respectively. Prostate volume and symptom severity were not statistically significant predictors of a rapid decline in peak urinary flow rate when variables were considered simultaneously (Roberts et al, 2000).

Based on TRUS, the growth of the prostate in these men 40 to 79 years old was estimated to be about 0.6 mL/yr or 6 mL per decade of life. However, prostate growth followed an exponential growth pattern, with a slope estimate of 0.4 mL/yr for men ages 40 to 59 years at baseline and of 1.2 mL/yr for those 60 to 79 years at baseline (Rhodes et al, 1995, 1999). An updated analysis revealed a median growth rate of about 1.9%/yr independent of age and symptoms. However, a higher baseline serum PSA and larger prostate volume predicted greater annualized volume increases.

Complications

Many of the complications of progressive BPH are rare, and much of the knowledge comes from studies of men presenting with such complications for treatment (i.e., cases) rather than observing cohorts of men for the development of complications.

Mortality

Between 1950 and 1954, 17 of 24 countries reported mortality rates of greater than 10 per 100,000, while between 1985 and 1989 data were available for 61 countries, with only one reporting a greater than 10 per 100,000 mortality rate (Boyle et al, 1996). If the mortality rates from 1950 were applied to 1990, 13,681 fewer deaths occurred in the United States alone than expected, a major but unheralded health care achievement.

Bladder Stones

In a large autopsy study the prevalence of bladder stones was eight times higher in men with a histologic diagnosis of BPH (3.4%) compared to controls (0.4%), but no increased incidence of ureteral or kidney stones was found (Grosse, 1990). In a study comparing watchful waiting and TURP in men with moderate symptoms, only 1 of 276 patients assigned to watchful waiting developed a bladder stone in 3 years of follow-up (Wasson et al, 1995). The self-reported rate of a bladder stone in a cross-sectional study in 2002 Spanish men was 0.7% (Hunter et al, 1996).

In clinical practice the risk of bladder stone development is small and screening is only indicated if clinical circumstances warrant it (e.g., hematuria, stuttering of urination).

Bladder Decomensation

Urologists search for a progression from a normal mucosa to advancing trabeculation and development of cellules and diverticula, with ultimate detrusor muscle failure in mind, when evaluating the bladder in men with BPH endoscopically. However, when the process starts, whether it really is related to BPH and obstruction, and when an intervention is necessary to prevent decomensation with resultant inability to void are unclear.

Biopsies from trabeculated, obstructed bladders show dense connective tissue deposition, a finding similar to that seen in animals experimentally obstructed (Gosling and Dixon, 1980; Levin et al, 1990, 2000; Chapple et al, 1991). However, bladder fibrosis is seen in both sexes with advancing age and may be a normal consequence of aging (Lepor et al, 1992a).

The critical question is whether or not delayed intervention might lead to progressive irreversible loss of bladder function and miss a window for cure. There is no direct evidence for this from longitudinal population or clinic patient studies. However, in a Department of Veterans Affairs (VA) cooperative study comparing watchful waiting with TURP, those patients who crossed over from the conservative arm to TURP later in the trial had not as significant an improvement in symptoms and flow rate compared to those who underwent TURP at the beginning after randomization (Flanigan et al, 1998).

Urinary Incontinence

Incontinence is one of the most feared complications from surgical intervention for BPH. While it may be the result of BPH secondary to overdistention of the bladder (overflow incontinence) or to detrusor instability estimated to affect up to one half or more of all obstructed patients (urge incontinence) (McConnell et al, 1994), it also is associated with aging, and in a community study an incidence of incontinence of 24% in men and 49% women over 50 years of age was reported (Roberts et al, 1998). In the VA cooperative study a 4% incidence of incontinence in both the surgical and conservative treatment arms was reported (Wasson et al, 1995). The self-reported rate of incontinence in a cross-sectional study in 2002

Spanish men was 6.1% (Hunter et al, 1996). In MTOPS the rate of socially unacceptable incontinence was 0.3 per 100 patient-years (McConnell et al, 2003).

Urinary Tract Infections

In older surgical series urinary tract infections (UTIs) constituted the main indication for surgical intervention in about 12% of patients (Holtgrewe et al, 1989; Mebust et al, 1989). Although one might intuitively assume that increased amounts of residual urine would predispose to the development of UTIs, clear evidence is lacking. Hunter and colleagues (1996) quoted a rate of 5.2% self-reported episodes of UTI in a cross-sectional survey of 2002 men in Madrid, Spain. The best data to date come from the MTOPS study, where the incidence of UTIs in the placebo-treated patients was only 0.1 per 100 patient-years (McConnell et al, 2003).

Upper Urinary Tract Deterioration and Azotemia

The AHCPR BPH guidelines reported a mean of 13.6% (range from 0.3% to 30%) of patients presenting for TURP with evidence of renal failure based on predominantly older studies (McConnell et al, 1994). Patients in renal failure have an increased risk for complications following TURP compared to patients with normal renal function (25% versus 17%) (Holtgrewe et al, 1989; Mebust et al, 1989), while the mortality increases up to sixfold (Holtgrewe and Valk, 1962; Melchior et al, 1974a, 1974b). In the large database of patients who had upper tract imaging prior to surgery, 7.6% of 6102 patients in 25 series had evidence of hydronephrosis, of whom one third had renal insufficiency (McConnell et al, 1994).

The term *silent obstruction* or *silent "prostatism"* has been used to describe the constellation of asymptomatic patients who eventually develop renal failure resulting from BOO, a situation both rare and important (Mukamel et al, 1979). In the VA cooperative study, only 3 of 280 surgically treated patients and 1 of 276 patients in the watchful waiting arm developed renal azotemia, defined as a doubling of serum creatinine from baseline (Wasson et al, 1995). In none of the cohort or population-based studies have cases of renal failure clearly attributable to BPH been reported. However, the self-reported rate of an episode of renal failure in a cross-sectional study in 2002 Spanish men was 2.4% (Hunter et al, 1996).

In MTOPS, there was not a single case of renal insufficiency resulting from BPH in over 3000 men followed for over 4 years (McConnell et al, 2003). However, one has to be careful not to overinterpret these findings. Participants in MTOPS were screened at baseline, and one might argue that some at higher risk for developing renal failure were excluded from participation.

Hematuria

It has always been recognized that patients with BPH might develop gross hematuria and form clots with no other cause being identifiable. Recent evidence suggests that, in those patients predisposed to hematuria, the microvessel density is higher compared to controls. Some renewed interest in the issue of BPH-related hematuria stems from the observation that finasteride appears to be a reasonable first-line therapy, apparently influencing the expression of VEGF (DiPaola et al, 2001). The self-reported rate of hematuria in a cross-sectional study in 2002 Spanish men was 2.5% (Hunter et al, 1996). Precise population estimates and incidence rates are not available, and the clinical management is dictated by the circumstances.

Acute Urinary Retention

Acute urinary retention (AUR) is for several reasons one of the most significant complications or long-term outcomes resulting from BPH. It has in the past represented an immediate indication for surgery. Between 25% and 30% of men who underwent TURP had AUR as their main indication in older series (Holtgrewe et al, 1989; Mebust et al, 1989), and today most patients failing to void

TABLE 103-16 Descriptive Studies on the Incidence of Acute Urinary Retention

after an attempt at catheter removal still undergo surgery. For this reason alone, AUR is from an economical standpoint as well as from the viewpoint of the patient an important and feared event. For the patient it presents as the inability to urinate without increasing pain, eventually a visit to the emergency room, catheterization, follow-up visits to the physicians, an attempt at catheter removal, and either recovery of spontaneous voiding or surgery, both a painful and time-consuming process. In older literature the risk of recurrent AUR was cited as being 56% to 64% within 1 week of the first episode, and 76% to 83% in men with diagnosed BPH (Breum et al, 1982; Klarskov et al, 1987; Hastie et al, 1990).

The etiology of AUR is poorly understood, and obstructive, myogenic, and neurogenic causes all may play a role (Kaplan et al, 2008). Prostate infection, bladder overdistention (Powell et al, 1980), excessive fluid intake, alcohol consumption, sexual activity, debility, and bed rest have all been mentioned (Stimson and Fihn, 1990). Prostatic infarction has been suggested as being an underlying event causing AUR (Graversen et al, 1989). Spiro and colleagues (1974) found evidence for infarction in 85% of prostates removed for AUR versus 3% of prostates in men having surgery for symptoms only. In contrast, in a study by Jacobsen and coworkers (1997) there was no evidence of infarction in six prostatectomy specimens removed from men who had surgery for AUR. Anjum and associates (1998) found fundamentally similar rates of infarction in 35 men with AUR versus 35 men with no AUR (1.9% versus 3.0%).

From a clinical and prognostic point of view, spontaneous AUR should be separated from precipitated AUR, although this is by no means consistently done in the literature. Precipitated AUR refers to the inability to urinate following a triggering event such as non-prostate-related surgery, catheterization, anesthesia, ingestion of medications with sympathomimetic or anticholinergic effects or antihistamines, or other events. All other

AUR episodes are classified as spontaneous (Roehrborn et al, 2000a). The importance of differentiating the two types of AUR becomes clear when evaluating the ultimate outcomes of patients. Following spontaneous AUR, 15% of patients had another episode of spontaneous AUR and a total of 75% underwent surgery, whereas after precipitated AUR, only 9% had an episode of spontaneous AUR and 26% underwent surgery (Roehrborn et al, 2000a).

Descriptive Epidemiology (Table 103-16). Older estimates of occurrence of AUR range from 4 to 15 to as high as 130 per 1000 person-years, as calculated by Jacobsen and colleagues (1997) based on published studies (Craigien et al, 1969; Birkhoff et al, 1976; Ball et al, 1981). This leads to 10-year cumulative incidence rates ranging from 4% to 73%. The self-reported rate of AUR in a cross-sectional study in 2002 Spanish men was 5.1% (Hunter et al, 1996).

More recent data from carefully controlled studies in better defined populations shed additional light on the incidence rates in community-dwelling men and clinical BPH populations. AUR occurred in the VA cooperative study over 3 years in 1 man after TURP and in 8 of 276 men in the watchful waiting arm, for an incidence rate of 9.6 per 1000 person-years (Wasson et al, 1995). Barry and coworkers (1997a) reported outcomes of 500 men, diagnosed with BPH by urologists, who were candidates for prostatectomy by established criteria but elected to be followed conservatively. In 1574 person-years, 40 episodes of AUR occurred at a constant rate throughout the 4 years of follow-up for an incidence rate of 25 per 1000 person-years.

During 15,851 person-years of follow-up in the Health Professionals Followup Study, 82 men reported an episode of AUR for an incidence rate of 4.5 per 1000 person-years (95% CI 3.1 to 6.2) (Meigs et al, 1999). Of the 2115 men ages 40 to 79 years in the Olmsted County Study, 57 had a first episode of AUR during 8344 person-years of follow-up (incidence rate of 6.8 per 1000 person-years, 95% CI 5.2 to 8.9) (Jacobsen et al, 1997).

Figure 103-22. Increase in incidence of acute urinary retention (AUR) with age in four large studies. (From Kaplan SA, Wein AJ, Staskin DR, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. *J Urol* 2008;180:47–54.)

The first excellent data from men diagnosed with BPH stem from PLESS (McConnell et al, 1998). In PLESS, 1376 placebo-treated men with enlarged prostates and moderate symptoms had complete follow-up over 4 years, of whom 99 experienced an episode of AUR for a calculated incidence rate of 1.8 per 100 person-years. The placebo treatment groups from three 2-year studies with a similar patient population were meta-analyzed by Boyle (1998). Of 2109 patients, 57 experienced AUR over the 2 years with a constant hazard for an incidence rate of 14 per 1000 person-years. In the MTOPS placebo group, the incidence rate was 0.6 per 100 patients-years for a cumulative incidence of 2%.

Analytical Epidemiology

Age. Several well-controlled studies provided considerable insights into the risk factors for AUR. Perhaps the most significant of these risk factors is age. Studies from European countries and the United States demonstrate a nearly linear increase in the age-specific incidence of AUR for men ranging in age from 40 to over 80 years (Jacobsen et al, 1997; Meigs et al, 1999; Verhamme et al, 2005; Cathcart et al, 2006) (Fig. 103-22).

Lower Urinary Tract Symptoms. Increased symptom severity is associated with increased risk of AUR in several large population-based or cohort studies (Table 103-17). In the Health Professionals Followup Study in men with mild symptoms, incidence of AUR increased from 0.4 per 1000 person-years for those 45 to 49 years old to 7.9 per 1000 person-years for those 70 to 83 years old. In men with symptom scores of 8 to 35, rates increased from 3.3 per 1000 person-years for those 45 to 49 years old to 11.3 per 1000 person-years for those 70 to 83 years old. Men with a clinical diagnosis of BPH and a symptom score of 8 or greater had the highest rates (age-adjusted incidence, 13.7 per 1000 person-years). All seven LUTS comprising the AUASI individually predicted AUR. The sensation of incomplete bladder emptying, having to void again after less than 2 hours, and a weak urinary stream were the best independent symptom predictors. Use of medications with adrenergic or anticholinergic side effects also predicted AUR (Meigs et al, 1999).

The Olmsted County Study analyses focused on age, symptom severity, maximum flow rate, and prostate volume (Jacobsen et al, 1997). Incidence rates per 1000 person-years for men in their 40s to their 70s increased from 2.6 to 9.3 if they had mild symptoms and from 3.0 to 34.7 if they had more than mild symptoms (see Table 103-17).

Urodynamic Parameters. The RR for AUR increased for older men, men with moderate to severe symptoms (3.2 times), those with a flow rate under 12 mL/sec (3.9 times), and those with a prostate volume greater than 30 mL by TRUS (3.0 times), all compared to a baseline risk of 1.0 for the corresponding groups

AUASI, American Urological Association Symptom Index; AUR, acute urinary retention; CI, confidence interval.

*Total of 82 AUR episodes in 6100 men with a crude incidence of 5.2/1000 patient-years (95% CI 4.1 to 6.4) in 15,851 patient-years of follow-up.

†Total of 57 AUR episodes in 2115 men with an overall incidence of 6.8/1000 patient-years (95% CI 5.2 to 8.9) in 8344 patient-years of follow-up.

From Kaplan SA, Wein AJ, Staskin DR, et al. Urinary retention and post-void residual urine in men: separating truth from tradition. *J Urol* 2008; 180:47–54.

(Fig. 103-23). The highest RR by proportional hazard models exists for 60- to 69-year-old men with more than mild symptoms and a flow rate of less than 12 mL/sec (10.3 times), and for 70- to 79-year-old men except if they had mild symptoms and a flow rate over 12 mL/sec. All other stratifications of men over 70 years had RRs ranging from 12.9 to 14.8 times (all compared to men 40 to

49 year old with mild symptoms and a flow rate over 12 mL/sec, for which the baseline risk is 1.0).

Prostate Volume and Serum PSA. While age in community-dwelling men is an important risk factor, in BPH trial populations of men who already are diagnosed with BPH, other factors can be analyzed. In the placebo groups of three 2-year studies (Marberger et al, 2000) and a 4-year study (PLESS) (McConnell et al, 1998; Kaplan et al, 2000; Roehrborn et al, 2000a) prostate volume, serum PSA, and symptom severity all were predictors of AUR episodes.

Over 4 years in PLESS, the incidence increased from 5.6% to 7.7% in men with a serum PSA of under 1.4 ng/mL from mild to severe symptoms, and from 7.8% to 10.2% for those with a serum PSA of over 1.4 ng/mL (Kaplan et al, 2000). In the 2-year

studies the rate of AUR was eightfold higher in those with a serum PSA of over 1.4 ng/mL (0.4% versus 3.9%), and threefold higher if the prostate volume was over 40 mL (1.6% versus 4.2%) (Marberger et al, 2000; Roehrborn et al, 2001). A detailed analysis showed a near-linear increase in risk for AUR with increasing thresholds of serum PSA (Fig. 103-24) in PLESS, an observation that applies to both spontaneous and precipitated AUR (Roehrborn et al, 1999c). The risk for both types of AUR increases with increasing serum PSA as well as prostate volume stratified by tertiles (Fig. 103-25). Similar observations were made in MTOPS, where the risk for AUR increased with increasing prostate volume as well as increasing baseline serum PSA (Fig. 103-26), as well as in the 2-year Phase III studies comparing dutasteride with placebo (Roehrborn

Serum prostate-specific antigen concentration is a powerful predictor of acute urinary retention and need for surgery in men with clinical benign prostatic hyperplasia. PLESS Study Group. *Urology* 1999;53:473–80.)

et al, 2002). An analysis of over 100 possible outcome predictors alone or in combination revealed a combination of serum PSA, urinating more than every 2 hours, symptom problem index, maximum urinary flow rate, and hesitancy as being only slightly superior to PSA alone in predicting AUR episodes (Roehrborn et al, 2001).

SURGERY FOR BENIGN PROSTATIC HYPERPLASIA

Both surgery and AUR represent distinct end points in the disease progression of BPH. There are, however, distinct differences. AUR is an outcome mandating management, and surgery is one of the commonly employed management styles. AUR is probably one of the clearer indications for surgery, leaving the treating physician little choice in a patient who failed a trial without catheter. However, most patients undergo surgery not for AUR but for symptoms (Holtgrewe et al, 1989). Depending on local practice pattern, AUR accounts for 5% to over 30% of the indications for surgery. AUR can be compared to a bone fracture. It is impossible for the physician in his or her interaction with the patient to increase or decrease the probability for that outcome to occur. Furthermore, once it has occurred, no interaction or consultation can undo it. In contrast, it is easy to see how patients can be influenced in their decision to undergo surgery by the consultation with the physician. The interaction style, the quoted probabilities of beneficial and harmful outcomes to occur, and many other factors cause considerable variability in the incidence rates of prostate-related surgery, an observation that caused the AHCPR to develop guidelines for the treatment of BPH (Wennberg et al, 1988). This situation is similar to that for myocardial infarction (MI) and coronary artery bypass graft (CABG). The analytical epidemiology of MIs is well understood, and risk factors are characterized. Not all MIs result in CABGs, and in fact CABGs are frequently performed for indications other than a recent MI. Consequently, there is abundant literature focusing on the geographic variation in the usage of CABG. From this brief discussion it becomes clear that surgery for BPH is a softer end point than AUR from an epidemiologic point of view, and data on rates of prostatectomy need to be interpreted in light of variation in its use, from provider to provider, region to region, health care plan to health care plan, and over time.

KEY POINTS: EPIDEMIOLOGY AND NATURAL HISTORY

- There is no globally accepted epidemiologic definition of BPH, and thus prevalence and incidence rates must be viewed in the context of the definitions chosen by the investigator reporting the data.
- Despite the significantly different proportion of men admitting to moderate to severe symptoms, a clear trend toward an increase in symptom scores with advancing age is noticeable in all reported studies.
- In general, in all cross-sectional studies prostate volume as assessed by TRUS has been found to increase slowly but steadily with advancing age.
- Analytical epidemiologic data suggest a limited role of classical determinants of the disease such as religion, socioeconomic factors, sexual activity, alcohol intake, hypertension, dietary factors, and others. There is conflicting evidence regarding smoking and some evidence suggesting dietary factors, obesity, and increased BMI as determinants of disease severity.
- All relevant parameters such as symptom severity and frequency, bother, interference, disease-specific HRQOL, maximum flow rate, and prostate volume tend to worsen with advancing age. However, reported correlations between these parameters as well as urodynamic pressure-flow studies are in general weak, with some exceptions. Strong correlations exist between measures of symptom severity and frequency (IPSS), bother, disease-specific HRQOL, and interference scores.
- The natural history of the disease has been studied in many longitudinal population-based studies as well as in placebo and sham control groups of treatment trials of men diagnosed with the condition. These studies suggest, in general, a worsening of LUTS and BPH with time. There are several key baseline parameters allowing a stratification of patients according to the risk of progression. Age, symptom severity, flow rate, prostate size, and serum PSA are useful predictors of the risk of progression.
- Complications of LUTS and BPH such as mortality, urinary tract infections, bladder decompensation, bladder stones, hematuria, urinary incontinence, upper urinary tract deterioration with renal insufficiency, and others are, in general, rare in properly supervised patients.
- The two most significant progression events are AUR and the need for BPH-related surgery. Although not exceedingly common, there is a significant baseline incidence rate and the risk is cumulative; that is, with increasing time of observation the incidence rate increases linearly.
- The risk of AUR and need for surgery is to some degree predictable from baseline parameters with advancing age, increased prostate size, and higher serum PSA levels representing the most significant risk factors.

Of all prostate surgeries, TURP and laser ablation of the prostate are still clearly the most common procedures and the best studied ones. Cross-sectional descriptive data on incidence rates are available from the Medicare database. While in 1962 TURP constituted over 50% of all major surgeries performed by American urologists, this number had dropped to 38% by 1986 (Holtgrewe et al, 1989; Mebust et al, 1989). Although the number of TURPs performed on Medicare patients declined from an all-time peak of 258,000 in 1987 to 168,000 in 1993—a reduction by 34%—it remains second only to cataract surgery on the list of Medicare's most costly surgical procedures. A 20% sample of Medicare beneficiaries was examined to further specify rates of TURP in the United States. In 1990, the rates of TURP (including all indications) were approximately 25, 19, and 13 per 1000 for men over the age of 75, 70 to 74, and 65 to 69, respectively. The 30-day mortality following TURP for the

treatment of BPH decreased from 1.20% in 1984 to 0.77% in 1990 (Lu-Yao et al, 1994). Compared to 1984 to 1990, age-adjusted rates of TURP for BPH during 1991 to 1997 declined further by approximately 50% for white (14.6 to 6.72 per 1000) and 40% for black (11.8 to 6.58 per 1000) men (Wasson et al, 2000). Medicare databases are only relevant to those men over 65 years enrolled in Medicare, and therefore are less interesting from a longitudinal epidemiologic point of view.

Older series of the natural history of BPH, such as the one reported by Craigen and colleagues (1969) projected somewhat unrealistic estimates of 35% incidence of prostatectomy at 1 year and 45% at 7 years. Diokno and coworkers (1992) reported an annual incidence rate of 2.6% and 3.3% for years 1 and 2 in his cohort of men followed longitudinally. Frequency, hesitancy, straining, and an interrupted stream were all associated with an increased risk.

The first study of substantial quality reporting on incidence rates and risk factors of prostate surgery was the Baltimore Longitudinal Study of Aging (Arrighi et al, 1990, 1991; Guess et al, 1990). Over 1000 men were followed for 30 years with yearly symptom assessments, questionnaires, and examinations. Age, incomplete emptying, and change in size and force of stream were all independently associated with the risk of prostate surgery, as was a reportedly enlarged prostate by DRE. Of 464 men without risk factors, only 3% required surgery during follow-up. For men with one risk factor the cumulative incidence was 9%, for those with two risk factors 16%, and for those with three risk factors 37%. In the VA Normative Aging Study, a similar study, nocturia and hesitancy emerged as independent predictors of surgery in 1868 men ages 49 to 68 followed for over 20 years (Epstein et al, 1991). Age and five LUTS (dysuria, incontinence, trouble initiating flow, nocturia, and slow stream) were associated with the risk of surgery in 16,219 men over 40 years enrolled in the Kaiser Permanente Health Plan in California, of whom 1027 men underwent prostatectomy over 12 years of follow-up (Sidney et al, 1991a, 1991b).

In the VA cooperative trial comparing surgery with watchful waiting, 65 of 276 (24%) patients assigned to watchful waiting crossed over to surgery within 3 years of follow-up, of whom 20 met predefined end points (azotemia, high residuals, incontinence, or high symptom scores). High baseline bother score was a strong predictor of requiring surgery (Wasson et al, 1995).

The probability of undergoing surgery over 4 years increased from 10% in those men diagnosed with BPH who had mild symptoms to 24% in those with moderate and 39% in those with severe symptoms at baseline, as reported in a natural history and observation study by Barry and coworkers (1997b).

The Olmsted County Study and the placebo-treated patients from the PLESS study provide additional insights into the risk factors for undergoing prostate surgery in either community-dwelling men or men enrolled in a BPH treatment trial.

In the Olmsted County Study, during more than 10,000 person-years of follow-up 167 men were treated, yielding an overall incidence of 16.0 per 1000 person-years. There was a strong age-related increase in risk of any treatment from 3.3 per 1000 person-years for men 40 to 49 years old to more than 30 per 1000 person-years for those 70 years old or older. Men with moderate to severe symptoms, depressed peak urinary flow rates (<12 mL/sec), enlarged prostate (>30 mL), or elevated serum PSA (≥ 1.4 ng/mL) had about four times the risk of BPH treatment as those who did not. After adjustment for all measures simultaneously, an enlarged prostate (hazard ratio 2.3, 95% CI 1.1 to 4.7), depressed peak flow rate (hazard ratio 2.7, 95% CI 1.4 to 5.3), and moderate to severe symptoms (hazard ratio 5.3, 95% CI 2.5 to 11.1) at baseline each independently predicted subsequent treatment. Overall nearly 1 in 4 men received treatment in the eighth decade of life. These data suggest that men with moderate to severe LUTS, impaired flow rates, or enlarged prostates are more likely to undergo treatment, with increases in risk of similar magnitude to those associated with adverse outcomes such as AUR (Jacobsen et al, 1999) (see Fig. 103-23).

Over 1500 patients with moderate LUTS and enlarged prostate glands were followed in the PLESS study on placebo for 4 years. Of these, 10% or 2.5% per year underwent surgery for BPH (McConnell et al, 1998). While the hazard of undergoing surgery was linear (i.e., it remained constant throughout the duration of the study), it was different when patients were stratified by either prostate volume or serum PSA in tertiles at the beginning of the study (Fig. 103-27). Similar to the incidence of AUR, the rates of surgery increased from 6.2% to 14.6% for patients in the lowest to the highest PSA tertile, and from 6.7% to 14.0% for patients in the lowest to the highest prostate volume tertile.

In MTOPS, the incidence of invasive therapy for BPH in the placebo group increased nearly linearly when stratifying by baseline serum PSA or prostate volume (Fig. 103-28) (McConnell et al, 2003).

Future Strategies for Nonsurgical Therapy for Male Lower Urinary Tract Symptoms

The term *benign prostatic hyperplasia* (BPH) has had very different connotations over the last 20 years. To the urologist, pathologist, radiologist, patient, and pharmaceutical companies it has had varying and often confusing meanings and definitions. It is important, however, that terminology be clear. Correctly speaking, BPH is a microscopic diagnosis characterized by cellular proliferation of the stromal and epithelial elements of the prostate, made by a pathologist. The radiologist or urologist may scan the prostate either with ultrasound or with three-dimensional imaging studies and confirm prostate enlargement, but this should be described as *benign prostatic enlargement* (BPE) (Haas and Resnick, 2000). To the urodynamicist, the hallmark of synchronous elevation of voiding pressure and a low urinary flow rate should be described as *bladder outlet obstruction* (BOO) (Nitti, 2000).

Most important, we need to move away from the practice of describing the constellation of lower urinary tract signs and symptoms that develop in the male population in association with aging and prostatic enlargement as BPH or clinical or symptomatic BPH and move toward the universal use of the term *lower urinary tract symptoms* (LUTS) to describe the clinical or symptomatic condition with which we are dealing (Abrams, 1994). The patient himself is typically concerned about the impact of his LUTS on quality of life rather than the presence of cellular proliferation, prostatic enlargement, or elevated voiding pressures. The transition from *clinical BPH* to *LUTS*, however, has been very variable over the last 20 years with regard to its adoption in different countries, with gradual acceptance by most national and international guidelines (Chapple and Abrams, 2013; Oelke et al, 2013). This transition has been delayed by the strong adoption by the pharmaceutical companies of BPH as a clinical syndrome and the acceptance by many of the regulatory authorities, such as the U.S. Food and Drug Administration (FDA), of the same terminology.

What we may have called *microscopic BPH* in the past is true histologic BPH; macroscopic BPH should be categorized as BPE, and clinical BPH as the complex of symptoms is more correctly called *LUTS*.

Histologic BPH describes a proliferative process of the stromal and epithelial elements of the prostate (Bartsch et al, 1979). The

proliferative process originates in the transition zone and the periurethral glands (McNeal, 1978; Shapiro 1990). It is rarely identified in males younger than 40 years (Berry et al, 1984). The autopsy incidence of BPH is age dependent, the proliferative process being present in approximately 70% and 90% of men in their seventh and ninth decades of life, respectively. The development of microscopic BPH requires aging and the testes as the source of androgens (Walsh, 1984). Androgens play a passive role in the proliferative process. The specific molecular events that initiate and promote histologic BPH have yet to be identified and characterized. Growth factors, such as epidermal growth factor (EGF), are involved through autocrine and paracrine stromal epithelial interactions (Steiner, 2000).

BPE can most easily be identified by digital rectal examination (DRE) and provides a relatively crude estimate of prostate size when compared with measurements obtained using transrectal ultrasonography (Bosch et al, 2005) or magnetic resonance imaging (MRI). Knowledge of prostate size may be clinically relevant in terms of selecting appropriate medical or surgical therapy. A strong correlation exists between serum prostate-specific antigen (PSA) levels and prostate volume (Roehrborn et al, 1999), and as a consequence, in the absence of adenocarcinoma, the PSA value may be used as a surrogate for prostate volume (Roehrborn et al, 2001). The transition zone (inner gland) accounts for the majority of BPH tissue. The transition zone volume can be quantified using transrectal ultrasonography (Lepor et al, 1994) or MRI (Tempany et al, 1993). There is no consensus regarding the extent of enlargement required to establish the diagnosis of BPE; however, prostate volume of approximately 20 mL may be regarded as normal (Garraway et al, 1991) before BPH develops, and volumes up to and greater than 100 mL are encountered clinically. Volumes greater than 30 to 40 mL appear to correlate with risk of LUTS and BPH progression (Jacobsen et al, 1997).

Patients may have LUTS, urinary retention, an overactive bladder (OAB), urinary tract infection (UTI), hematuria, or renal insufficiency (Jepsen and Bruskewitz, 2000). Historically, the pathophysiology of LUTS was often attributed to BOO secondary to BPE. This hypothesis was supported by epidemiologic data suggesting that the prevalences of BPH, BPE, and LUTS are age

dependent and therefore causally related (Isaacs and Coffey, 1989). This rather overly simplistic concept of the pathophysiology of LUTS has been challenged by more recent reports demonstrating only weak relationships among prostate size, severity of BOO, and severity of symptoms (Barry et al, 1993; Bosch et al, 1995; Girman et al, 1995; Yalla et al, 1995; Chapple and Abrams, 2013). However, there are numerous epidemiologic data to confirm that LUTS or histologic BPH is a slowly progressive condition and that men with a larger prostate (or higher PSA) are at significantly greater risk of LUTS progression, impaired quality of life, and complications such as acute urinary retention (AUR) (Roehrborn et al, 2001).

The International Consultation on Urological Diseases' (ICUD's) 6th International Consultation on New Developments in Prostatic Diseases and Prostate Diseases on male LUTS endorsed the appropriate use of the current terminology—namely, *lower urinary tract symptoms, benign prostatic hyperplasia, benign prostate enlargement, and benign prostatic obstruction*—and recommended that terms such as *clinical benign prostatic hyperplasia* or the *benign prostatic hyperplasia patient* be abandoned (Chapple and Abrams, 2013).

Adoption of this correct terminology is particularly important when treating the male patient with the OAB and especially patients with nocturia.

DIAGNOSIS

The complex of symptoms (LUTS) is not specific for BPH, BPE, or BOO. It is advantageous, however, that LUTS describes the symptoms without attributing a cause. LUTS is not sex, age, or disease specific (Abrams, 1994). The risk of using the term *clinical BPH* is that it gives a false diagnostic permission to treat the patient, which may be translated into treatment without a proper diagnosis (Chapple and Abrams, 2013).

The initial diagnostic challenge in these patients is to establish that the symptoms are, in fact, a result of benign prostate disease. This is the primary focus of initial evaluation and diagnostic testing. Fortunately, nonprostatic causes of symptoms can be excluded in a significant majority of patients on the basis of history, physical examination, and urinalysis. Additional diagnostic testing is necessary in patients in whom the diagnosis is still unclear after initial evaluation. These tests may also have a modest (but still unproven) value in predicting the response to treatment. The following recommendations concerning the initial evaluation of men with LUTS reflect the consensus opinion for several independent groups. The American Urological Association (AUA) BPH guidelines committee reported in 1994, 2003, 2006, and 2010 (McVary et al, 2011). The European Association of Urology (EAU) has also published guidelines on the treatment and follow-up of non-neurogenic male lower urinary tract symptoms including benign prostatic obstruction (Oelke et al, 2013). Algorithms for the management of LUTS and BPH are shown in Figures 104-1 to 104-3.

Initial Evaluation

Medical History

A detailed medical history should be taken to identify other causes of voiding and storage dysfunction or comorbidities that may complicate treatment. Specific additional areas to discuss when taking the history of a man with LUTS include a history of hematuria, UTI, diabetes, nervous system disease (e.g., Parkinson disease or stroke), urethral stricture disease, urinary retention, and aggravation of symptoms by cold or sinus medication. Current prescription and over-the-counter medications should be considered to determine whether the patient is taking drugs that impair bladder contractility (anticholinergics) or that increase outflow resistance (sympathomimetics). A history of prior lower urinary tract surgery raises the possibility of urethral or bladder neck stricture. Use of a bladder diary and frequency-volume chart (recording times and volume) will help identify patients with polyuria or other nonprostatic disorders.

Physical Examination

A DRE and a focused neurologic examination should usually be performed. In addition, examination of the external genitalia is indicated to exclude meatal stenosis or a palpable urethral mass, and an abdominal examination is necessary to exclude an overdistended, palpable or percussable bladder. The DRE and focused neurologic examination are performed to detect prostate or rectal malignancy, to evaluate anal sphincter tone, and to rule out any neurologic problems that may cause the presenting symptoms. The presence of induration is as important a finding as the presence of a nodule and should be correlated with a serum PSA value so that the need for prostatic biopsy can be assessed and acted on.

DRE establishes the approximate size of the prostate gland. Estimation of prostate size is important to guide the most appropriate pharmacologic or interventional approach. DRE provides a sufficiently accurate measurement in most patients. The size of the prostate is not critical in deciding whether active treatment is required. Prostate size does not correlate precisely with symptom severity, degree of urodynamic obstruction, or treatment outcomes (Roehrborn et al, 1986; Simonsen et al, 1987). If a more accurate measurement of prostate volume is needed to determine whether to perform open prostatectomy rather than transurethral resection of the prostate (TURP) or some other procedure such as laser vaporization or enucleation, ultrasound (transabdominal or transrectal) (Bosch et al, 2005) or MRI scanning is more accurate than cystourethroscopy. A larger gland, and consequently a higher PSA, is associated with a greater risk of BPH progression (Roehrborn et al, 2001).

Urinalysis

A urinalysis should be done by use of either a dipstick test or microscopic examination of the spun sediment to rule out UTI and hematuria, either of which strongly suggests a non-BPH pathologic process as a cause of symptoms. Because serious urinary tract disorders are relatively uncommon, the positive predictive value of screening for them is low, and the effectiveness of early detection and intervention is unproven. However, in older men with LUTS and a higher prevalence of these disorders, the benefits of an innocuous test such as urinalysis clearly outweigh the harms involved. The test permits the selective use of renal imaging and endoscopy for patients with the greatest chance of benefiting from them. More important, urinalysis assists in distinguishing UTIs and bladder cancer from benign prostate disease. These conditions may produce urinary tract symptoms (e.g., frequency and urgency) that mimic LUTS or BPH. If a dipstick approach is used, a test that includes leukocyte esterase and nitrite tests for the detection of pyuria and bacteriuria should be used.

The positive predictive value of urinalysis for cancer or other urologic diseases is around 4% to 26%, depending on the patients screened and the rigor of follow-up studies (Mohr et al, 1986; Messing et al, 1987; Mohr et al, 1987). Urine cytology should always be requested in men with severe storage symptoms and dysuria, especially if they have a smoking history. Carcinoma in situ of the bladder may have serious consequences if overlooked.

Serum Creatinine Measurement

Although the measurement of serum creatinine was recommended in the initial evaluation of all patients with LUTS to exclude renal insufficiency caused by the presence of obstructive uropathy (McConnell et al, 1994; Denis et al, 1998), at the Fifth International Consultation on BPH it was suggested that serum creatinine determination should be optional. The AUA guidelines on BPH no longer recommend routine creatinine measurement in the standard patient. However, it is well established that patients with renal insufficiency have increased risk for postoperative complications. The risk is 25% for patients with renal insufficiency, compared with 17% for patients without the condition (Mebust et al, 1989). Moreover, the mortality increases up to sixfold for patients

BASIC MANAGEMENT OF LUTS IN MEN

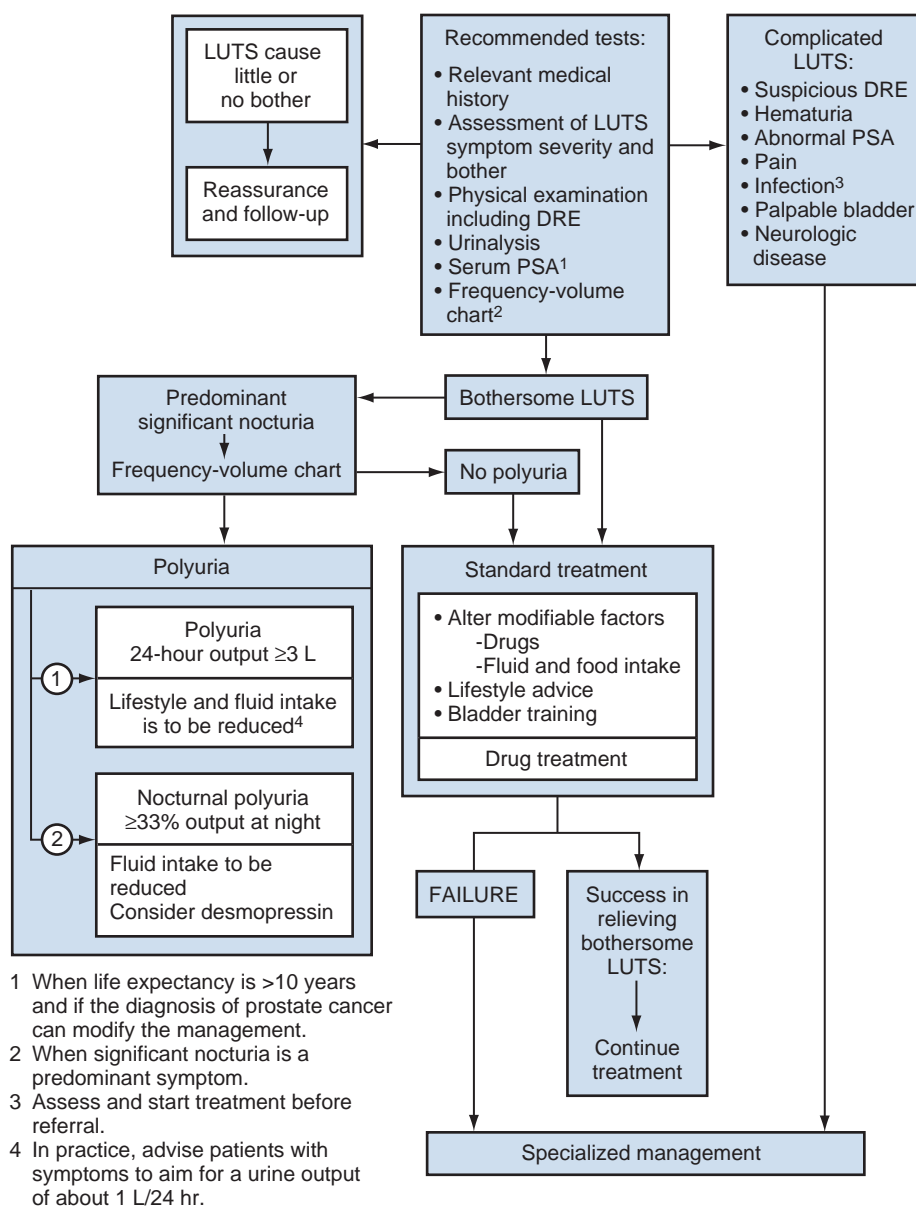

Figure 104-1. International consensus guideline (2009) algorithm for management of lower urinary tract symptoms (LUTS): basic management. DRE, digital rectal examination; PSA, prostate-specific antigen. (From Abrams P, Chapple C, Khoury S, et al. Evaluation and treatment of lower urinary tract symptoms in older men. *J Urol* 2009;181[4]:1779–87.)

treated surgically if they have renal insufficiency (Holtgrewe and Valk, 1962; Melchior et al, 1974). Of 6102 patients evaluated in 25 studies by intravenous urography (IVU) before prostate surgery, 7.6% had evidence of hydronephrosis (McConnell et al, 1994). Of these patients, 33.6% had associated renal insufficiency. Elevated serum creatinine in a patient with LUTS is an indication for imaging studies (usually ultrasound) to evaluate the upper urinary tract. In a retrospective analysis of 345 patients who had undergone prostatectomy, 1.7% ($n = 6$) had occult and progressive renal damage (Mukamel et al, 1979). These patients had minimal or no urinary symptoms. Measurement of serum creatinine is one modality to identify such at-risk patients. In a recent large-scale study of older Korean men ($N = 3713$), those with severe LUTS and prostate enlargement were at increased risk of deteriorating renal function irrespective of prostate volume (Kwon et al, 2012). Creatinine assessment was recommended in the 2013 ICUD guideline on male LUTS (Chapple and Abrams, 2013).

Serum Prostate-Specific Antigen

Prostate cancer can lead to LUTS by producing bladder outflow obstruction similar to BPH. Moreover, localized prostate cancer commonly coexists with BPH. In most men with a 10-year or greater life span, the knowledge of concomitant prostate cancer may well alter management of LUTS. The detection of a large nodular prostate cancer on DRE would no doubt alter therapy; however, the early detection of small-volume prostate cancer in an 80-year-old man is unlikely to increase life expectancy. A PSA test and DRE increase the detection rate of prostate cancer over DRE alone. **Therefore, measurement of the serum PSA value should be performed in patients in whom the identification of cancer would clearly alter LUTS management** (Abrams et al, 2009; McVary et al, 2011; Oelke et al, 2013). There is significant overlap between the serum PSA values of men with BPH and men with clinically localized prostate cancer. Twenty-eight percent of men with histologically proven BPH

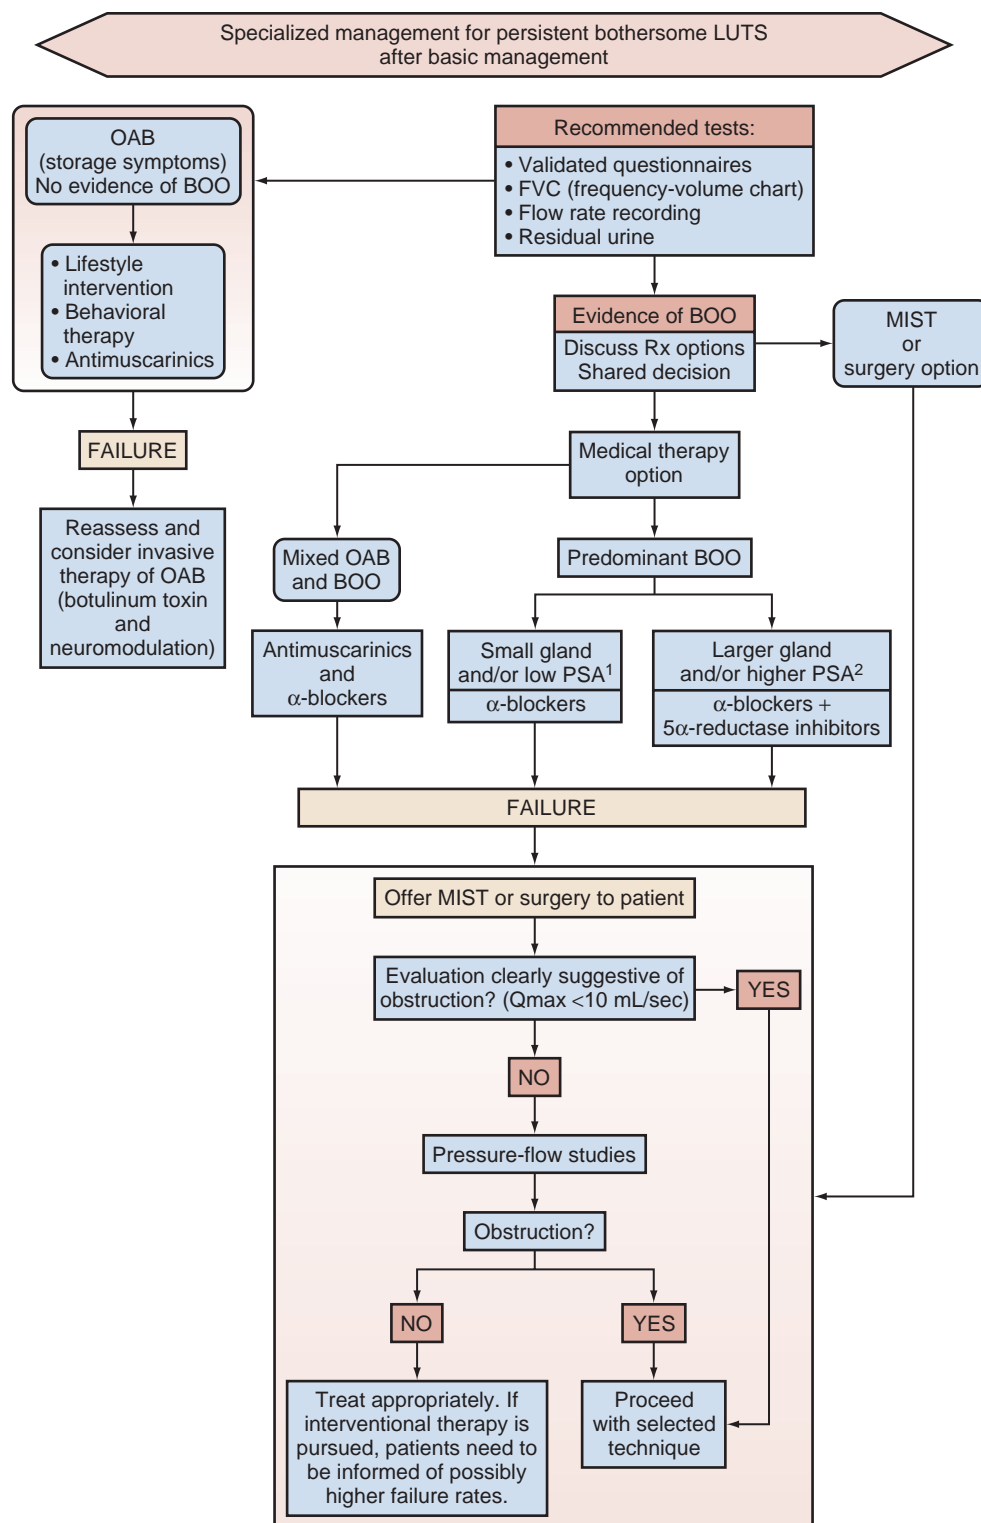

Figure 104-2. International consensus guideline (2009) algorithm for management of lower urinary tract symptoms (LUTS): specialized management. 1, PSA <1.5 ng; 2, PSA >1.5 ng; BOO, bladder outlet obstruction; MIST, minimally invasive surgical treatment; OAB, overactive bladder; PSA, prostate-specific antigen; Rx, treatment. (From Abrams P, Chapple C, Khoury S, et al. Evaluation and treatment of lower urinary tract symptoms in older men. *J Urol* 2009;181[4]:1779–87.)

have a serum PSA greater than 4.0 ng/mL (McConnell et al, 1994). Serum PSA trends over time (PSA velocity), measurement of free versus complexed PSA, and PSA density may help to improve the specificity of PSA in men with BPH. Newer markers such as the p2PSA and Prostate Health Index (PHI) score (Lazzeri et al, 2013)

or urinary PCA3 test result can also help to differentiate BPH from prostate cancer.

In the absence of prostate cancer, the PSA value provides a guide to prostate volume, an indication of the likelihood of response to therapy with 5α-reductase inhibitors, and an

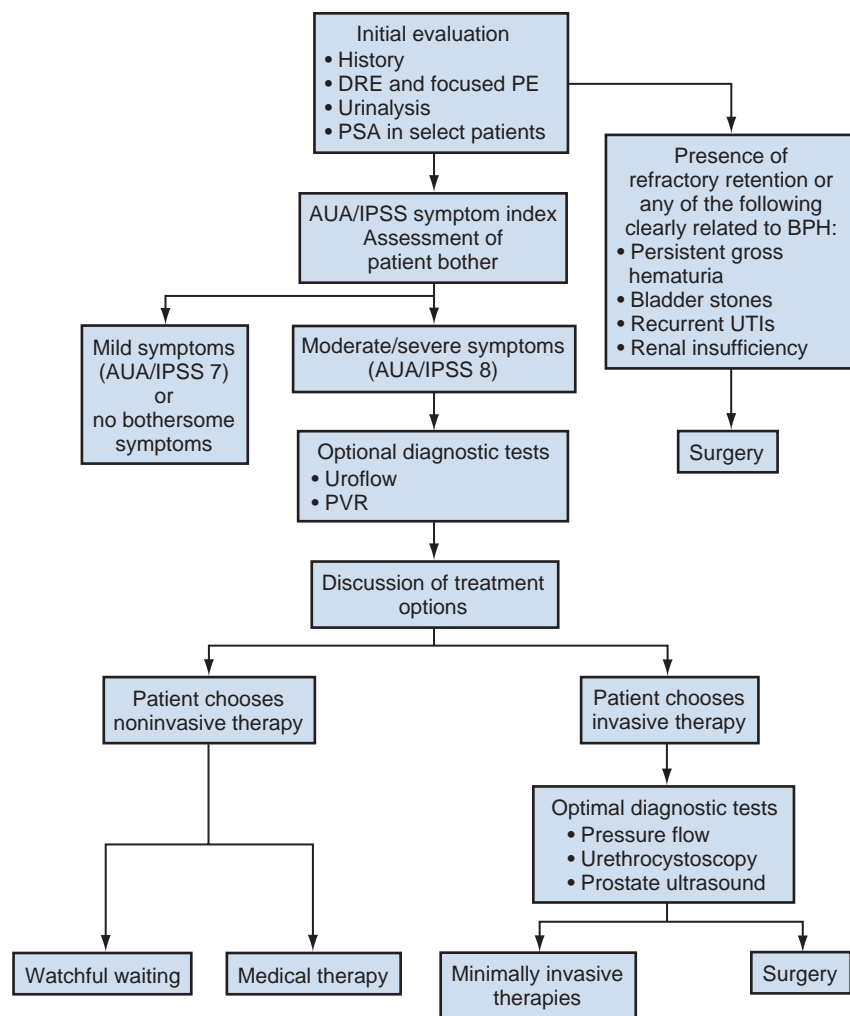

Figure 104-3. American Urological Association (AUA) guideline algorithm for management of benign prostatic hyperplasia (updated 2006). DRE, digital rectal examination; IPSS, International Prostate Symptom Score; PE, physical examination; PSA, prostate-specific antigen; PVR, post-void residual; UTI, urinary tract infection. (From Kaplan SA. Update on the American Urological Association guidelines for the treatment of benign prostatic hyperplasia. *Rev Urol* 2006;8[Suppl. 4]:S10–7.)

indication of the risk of LUTS or BPH progression. However, in men with LUTS already treated with a 5 α -reductase inhibitor (e.g., finasteride or dutasteride) serum PSA is reduced 40% to 50% after 12 months of treatment (Guess et al, 1993). Failure to establish a baseline (pretreatment) PSA level may therefore complicate interpretation of future PSA values. Men who are taking these agents should have their PSA value doubled to correctly assess their risk of harboring a prostatic adenocarcinoma and should be watched for any increase from nadir values. Provided that this is done, recent evidence suggests that 5 α -reductase therapy actually increases the sensitivity of PSA as a detector of cancer (Andriole et al, 2011).

Symptom Assessment

The AUA Symptom Index or the identical International Prostate Symptom Score (IPSS) is recommended as the symptom scoring instrument to be used for the baseline assessment of symptom severity in men with LUTS (Abrams et al, 2009, McVary et al, 2011). When this system is used, symptoms can be classified as mild (0 to 7), moderate (8 to 19), or severe (20 to 35) (Barry et al, 1992b). The symptom score should also be the primary determinant of treatment response or disease progression in the follow-up period. Although other symptom score questionnaires are used, the IPSS is now the U.S. and international standard.

However, the IPSS cannot be used to establish the diagnosis of LUTS or BPH. Men (and women) with a variety of lower urinary tract disorders (e.g., infection, tumor, neurogenic bladder disease) will have a high IPSS. Nonetheless, the IPSS is a good instrument to grade baseline symptom severity, assess the response to therapy, and detect symptom progression in men managed by watchful waiting. Optimal treatment decisions in individual patients will also need to take into account how a given level of symptoms affects each man's quality of life (degree of bothersomeness).

The IPSS was developed from the AUA score developed by the measurement committee of the AUA (Barry et al, 1992a, 1992b). Each question on the IPSS can yield 0 to 5 points, producing a total symptom score that can range from 0 to 35. This seven-question set is internally consistent (Cronbach alpha, 0.85) and reliable (test-retest correlation, 0.93). The index correlates strongly with patients' global ratings of their urinary difficulties ($r = 0.78$) and is sensitive to treatment response.

Johnson and colleagues (2009) showed that patients with a low education status are more likely to misunderstand the American Urological Association Symptom Score whether they are managed in a public hospital or a university practice. They tend to misrepresent their symptoms and therefore may receive inappropriate treatment. Eight percent of university hospital and almost 25% of public

hospital patients under-reported their moderate symptoms as mild, and 33% of university hospital and 16% of public hospital patients over-reported their mild symptoms as moderate. When the questionnaire is administered by a medical professional (even though the questionnaire is recommended to be “self-administered”), many of the inaccuracies disappear. The use of the additional bother score or quality-of-life scale may usefully guide appropriate treatment.

Although the IPSS correlates well with quality of life measures (Sagnier et al, 1995), there is still a need for sensitive LUTS- and BPH-specific quality-of-life instruments. Furthermore, because storage symptoms often predominate, there is a need for better methods of quantifying urgency and frequency and recording any incontinence. The standardization subcommittee of the International Continence Society has usefully categorized the range of likely symptoms into three groups: storage, voiding, and postmicturition (Abrams et al, 2003). Subdividing the IPSS into the four obstructive and three storage questions may also be useful. There is now level 1 evidence that recording an IPSS helps to identify patients with LUTS presumed to be secondary to benign prostatic obstruction and that it can be used to monitor change with treatment. A modified short form of the AUA Symptom Index known as the UWIN has also been validated (Barqawi et al, 2011). The AUA Symptom Index and the UWIN were correlated well in a study of 278 men (Crawford et al, 2011). A series of other systems (such as the King's Health Questionnaire, International Consultation on Incontinence Modular Questionnaire on male LUTS [ICIQ-MLUTS], Danish Prostatic Symptom Score [DAN-PSS], and Overactive Bladder Symptom Score [OABSS]) may be more sensitive to changes in storage symptoms or useful for research studies. **A voiding diary with frequency and volume recordings may also be helpful**, especially in the presence of significant nocturia (Weiss, 2006; Chapple and Abrams, 2013). These should be recorded for a minimum of 3 days and ideally for 7 days (Homma et al, 2002).

Clearly, symptom scores alone do not capture the complete picture of a prostate problem as perceived by the individual patient. Symptom impact on a patient's lifestyle must be considered as well. An intervention may make more sense for a moderately symptomatic patient who finds his symptoms very bothersome than for a severely symptomatic patient who finds his symptoms quite tolerable.

Additional Diagnostic Tests

Additional testing should be considered after the initial evaluation if there is a significant chance the patient's LUTS may not be the result of BPH or BOO. Patients with normal initial evaluation findings and only mild symptomatology on the IPSS (scores 0 to 7), or even those who have moderate symptoms but are minimally bothered, do not need additional diagnostic evaluation and can be considered for simple monitoring and observed (Kaplan, 2006). Men who have developed serious complications should be treated surgically in most cases. Urinary flow rate, postvoid residual (PVR) urine, and pressure-flow urodynamic studies are appropriate tests to consider in the evaluation of men with moderate to severe symptoms (IPSS 8 to 35). The value of pressure-flow studies is debatable, especially in men who elect watchful waiting or medical therapy as their management option. **Cystoscopy should not be done routinely** but is optional during later evaluation if invasive treatment is strongly considered. Urinary flow rate and PVR are generally recommended tests, and frequency-volume chart recordings are recommended by most (Abrams et al, 2009; Jones et al, 2010; McVary et al, 2011; Oelke et al, 2013).

It may be appropriate for the physician to offer treatment alternatives to the patient without performing any further diagnostic tests. Especially if the patient chooses watchful waiting or non-invasive therapy, invasive diagnostic tests may not be necessary. Conversely, if the patient elects an invasive treatment option, it may be appropriate for the physician to consider further evaluation.

Diagnostic Tests in Men Who Require Surgery for Lower Urinary Tract Symptoms or Benign Prostatic Hyperplasia

In general, surgery is recommended if the patient has refractory urinary retention (failing at least one attempt of catheter removal) or high-pressure chronic retention (HPCR) or any of the following conditions clearly secondary to BPE or BOO: recurrent UTI, recurrent gross hematuria (resistant to 5 α -reductase inhibitor therapy), bladder stones, renal insufficiency, or large bladder diverticula (Abrams et al, 2009; National Institute for Health and Care Excellence [NICE], 2010; McVary et al, 2011; Oelke et al, 2013). If there is reason to suspect that the patient's retention may be a result of detrusor hypocontractility, then urodynamic studies (e.g., filling cystometry) may be helpful. Pressure-flow urodynamic studies are not informative if the patient cannot urinate. Cystoscopy may be helpful to consider before the operative procedure to help plan the most prudent approach. The presence of infection and hematuria in patients should prompt appropriate evaluation and therapy for these conditions before treatment of LUTS.

Uroflowmetry

In general, uroflowmetry is recommended (by the AUA [McVary et al, 2011]) for specialist investigation (sixth International Consultation [Abrams et al, 2009]) or is required before invasive treatment (EAU [Oelke et al, 2013]). Uroflowmetry involves the electronic recording of the urinary flow rate throughout the course of micturition. It is a common, noninvasive urodynamic test used in the diagnostic evaluation of patients with symptoms of BOO. The results of uroflowmetry are nonspecific for causes of the symptoms. For example, an abnormally low flow rate may be caused by an obstruction (e.g., hyperplastic prostate, urethral stricture, meatal stenosis) or by detrusor hypocontractility. The Agency for Healthcare Research and Quality guideline panel reached the following conclusions regarding uroflowmetry (McConnell et al, 1994), which still apply:

- Flow rate measurements are inaccurate if the voided volume is less than 125 to 150 mL.
- Flow rate recording is the single best noninvasive urodynamic test to detect lower urinary tract obstruction. Current evidence, however, is insufficient to recommend a given cutoff value to document the appropriateness of therapy.
- The peak flow rate (PFR; Qmax) more specifically identifies patients with BOO than does the average flow rate (Qave).
- Although Qmax decreases with advancing age and decreasing voided volume, no age or volume correction is currently recommended for clinical practice.
- Although considerable uncertainty exists, patients with a Qmax greater than 15 mL/sec appear to have poorer treatment outcomes after prostatectomy than patients with a Qmax of less than 15 mL/sec.
- A Qmax of less than 15 mL/sec does not differentiate between obstruction and bladder decompensation (or detrusor underactivity, which is present in 9% to 48% of men undergoing urodynamic evaluation for non-neurogenic LUTS) (Osman et al, 2014).

Despite its limitations, flow rate recording has demonstrated some sensitivity in identifying BOO resulting from BPE. Scott and coworkers (1967) and Shoukry and associates (1975) found that Qmax correlated better than symptoms with the presence or absence of obstruction as determined by pressure-flow studies. Siroky and coworkers (1979) concluded that uroflowmetry was able to separate physiologically unobstructed and obstructed patients. Gleason and colleagues (1982) found that Qmax distinguished between normal men and patients with BPE, urethral stricture, or prostatitis. However, they also noted that a subgroup of patients with a decompensated detrusor muscle could not be separated from the obstructed men on the basis of Qmax alone.

Chancellor and colleagues (1991) found that flow rate recording cannot distinguish between BOO and impaired detrusor contractility as the cause for a low Qmax. None of eight measured,

noninvasive urodynamic parameters was significantly different for 31 patients with outlet obstruction than for 14 patients with impaired detrusor contractility. Abrams and associates studied the value of uroflowmetry before prostatectomy (Abrams, 1977; Abrams et al, 1979). Failure rates for surgery were found to decrease with the addition of flow rate measurement to symptom assessment in preoperative evaluation.

Qmax appears to predict surgical outcome in some studies. In one study reported by Jensen and coworkers (1984), 53 patients underwent prostatectomy based on clinical indication alone. All three groups according to level of Qmax experienced improvements in symptom score after surgery, but the group with a Qmax less than 10 mL/sec before treatment had a better overall subjective outcome as assessed by global subjective judgment.

In another study, which included men studied with flow rates before and 6 months after prostatectomy (Jensen et al, 1988a), subjective evaluation revealed an overall symptomatic improvement rate of 80% after surgery. The difference in success rates for men falling above or below the cutoff value of Qmax of 10 mL/sec was not significant ($P = .2$). When a Qmax cutoff of 15 mL/sec was used, success rates for men above or below the cutoff value differed significantly.

McLoughlin and coworkers (1990), using urodynamic testing and a cutoff value of 12 mL/sec, evaluated 108 men with clinical BPH before and 1 year after surgery and determined that with use of a Qmax cutoff of less than 12 mL/sec as an indicator for obstruction, only 3% of patients would have been subjected to an unnecessary TURP. These authors believed that routine pressure-flow studies or cystometrograms were not indicated, but that the screening of flow rates followed by further urodynamic testing in patients with a Qmax greater than 12 mL/sec should be considered. Very low rates do not appear to portend poor treatment outcome. In one study of 84 patients undergoing surgery for symptomatic BPH (Donkervoort et al, 1975), patients with a preoperative Qmax less than 7 mL/sec improved symptomatically as much as patients with a Qmax greater than 7 mL/sec.

Neither subjectively assessed symptoms nor quantified symptom-score analyses correlate strongly with uroflowmetry measurements; they are independent assessments. Patients with a PFR greater than 15 mL/sec may have somewhat poorer outcomes after surgery than those with a Qmax less than 15 mL/sec (although the majority of patients still improve). Other investigators report similar findings for different Qmax cutoff values (e.g., 12 mL/sec). Patients with very bothersome LUTS suggestive of BOO but having a Qmax greater than 15 mL/sec may benefit from further urodynamic testing (i.e., pressure-flow studies) to reduce the number of surgical treatment failures.

Postvoid Residual Urine

PVR urine is the volume of fluid remaining in the bladder immediately after the completion of micturition. Studies indicate that PVR urine normally ranges from 0.09 to 2.24 mL, with the mean being 0.53 mL (Hinman and Cox, 1967). Seventy-eight percent of normal men have PVR values of less than 5 mL, and 100% have volumes of less than 12 mL (Di Mare et al, 1963). The AHCPH BPH guideline panel reached the following conclusions regarding PVR (McConnell et al, 1994):

- Residual urine volume measurement has significant intraindividual variability that limits its clinical usefulness.
- Residual urine volume does not correlate well with other signs or symptoms of LUTS and BPH.
- Large residual urine volumes may predict a slightly higher failure rate with a strategy of watchful waiting. However, the threshold volume defining a poorer outcome is uncertain.
- It is uncertain whether residual urine volume predicts the outcome of surgical treatment.
- It is uncertain whether residual urine volume indicates impending bladder or renal damage.
- Residual urine volume can be measured with sufficient accuracy noninvasively by transabdominal ultrasonography.

The Fourth International Consultation initially recommended PVR determination in the initial assessment and during monitoring of patients under watchful waiting or other conservative treatment regimens (Denis et al, 1998). However, the latest male LUTS ICUD report (Chapple and Abrams, 2013) states that the level of evidence for PVR in the standard patient is weak and based mainly on expert opinion—that is, a level 5, grade D recommendation.

PVR measurement can be performed by noninvasive (ultrasound) and by invasive (catheterization) methods. Invasive techniques are accurate if performed correctly but carry a small but clinically significant risk of discomfort, urethral injury, UTI, and transient bacteremia. Small portable and less expensive devices can be used to measure PVR, with reported accuracy comparable to that with more expensive ultrasound units and catheterization. Birch and coworkers (1988) reported that of 30 men with BPH, 66% had wide variations in PVR when three measurements were done on the same day. In 34% of patients, there was no difference among the three measurements. In 58%, at least two volumes were significantly different. In 8% of patients, all three were different. In most patients, two measurements were statistically similar whereas the third one yielded quite different results. Bruskewitz and colleagues (1982) found similarly wide variations of the measured amount when they performed repetitive measurements of PVR (repeated two to five times) by in-and-out catheterization on 47 men before prostatectomy. They also found no correlation between the amount of residual urine and any cystoscopic or urodynamic findings, symptoms, or the presence or absence of a history of UTIs. Most clinical studies demonstrate minimal correlation between PVR and baseline measurements of symptoms, flow rate, or urodynamic measures of obstruction (Griffiths and Castro, 1970; Shoukry et al, 1975; Abrams and Griffiths, 1979). However, Neal and associates (1987) found a significant association in 253 men among PVR, age, “below-normal” Qmax, and high urethral resistance. Low voiding pressure, however, did not correlate well with PVR. The authors concluded that outflow obstruction is related to the development of increasing amounts of PVR urine. In the AUA outcome study, Barry and colleagues (1993) found a significant correlation between high PVR and low flow rates but no correlation with IPSS.

Traditionally, urologists have assumed that increasing amounts of PVR denote LUTS or BPH progression and are thus an indication for surgery. This concept underlies the common inclusion of PVR in each individual government’s appropriateness criteria. Unfortunately, data are lacking to support the predictive value of PVR. Andersen (1982) studied 104 men with BPH and reported two patterns of BPH progression. The slow course was characterized by the development of high levels of PVR that resulted in decompensation of the detrusor muscle and eventually led to urinary retention. The fast course was associated with uninhibited detrusor contractions (UDCs). The amount of PVR, the presence of UDCs, and symptoms correlated poorly in the study. Nevertheless, Andersen recommended PVR as a safety parameter when measured longitudinally throughout the clinical course of a patient with prostatism.

Data from the Veterans Affairs (VA) Cooperative Study Group randomized trial comparing TURP with watchful waiting demonstrated that PVR does not predict the outcome of surgery, and there was little evidence to support criteria that require a certain amount of PVR before surgery is justified (Wasson et al, 1995). In addition, high PVR did predict a slightly higher failure rate for watchful waiting. However, the majority of men with large residual urine volume did not require surgery during the 3-year duration of the trial. In summary, PVR is best viewed as a safety parameter. Men with significant PVR should certainly be monitored more closely if they elect nonsurgical therapy, particularly if antimuscarinic therapy is chosen.

Pressure-Flow Studies

If the initial evaluation, flow rate, and PVR are not sufficiently suggestive of BOO, further urodynamic assessment by pressure-flow studies should be considered, especially if an invasive treatment is

considered (i.e., surgery) or if surgical treatment has failed (McConnell et al, 1994; Denis et al, 1998; Abrams et al, 2009; McVary et al, 2011). Pressure-flow studies differentiate between patients with a low Qmax secondary to obstruction and those whose low Qmax is caused by impaired detrusor contractility. They should be performed when the distinction between the two will affect therapeutic decisions. Patients with a history of neurologic diseases known to affect bladder or sphincteric functions, as well as patients with normal flow rates (Qmax > 15 mL/sec) but bothersome symptoms, may also benefit from urodynamic evaluation, especially if surgical therapy is contemplated.

The value of pressure-flow measurement in predicting treatment outcome is uncertain. In a study by Abrams and colleagues (1979), the inclusion of pressure-flow data in the preoperative evaluation and indication for surgery reduced the subjective failure rate to 12%, down from 28% when patients were certified as candidates for surgery without the urodynamic data. However, a 28% failure rate is significantly higher than that reported in other TURP series (McConnell et al, 1994). Jensen and Andersen (1990) recommended invasive urodynamic testing for patients with a Qmax greater than 15 mL/sec. For the population in their study, this would have resulted in an additional 9% of patients being excluded from surgery and a decrease in failure rate to 8.3%. The support for this recommendation may be questioned, however, in light of earlier work by Jensen and coworkers (1988b, 1988c) that found most unsatisfied patients are incorrectly classified preoperatively even with urodynamic testing.

Pressure-flow studies do permit more accurate categorization of patients. Abrams and associates (1979) used pressure-flow plots in addition to flow rate measurement. The study found that in about half the cases the patients with LUTS could be correctly classified as obstructed or nonobstructed by Qmax alone, but that the addition of the detrusor pressure at Qmax allowed correct classification in two thirds of the group. The remaining one third of the patients were assessed by pressure-flow plot. In many of these patients, both pressure and Qmax were low, indicating a decompensating detrusor muscle as the source for the low Qmax.

Pressure-flow studies provide much more specific insight into detrusor function and the cause of voiding dysfunction than do flow rate measurements. However, a number of outcome-based investigations demonstrate a modest additional value of pressure-flow studies over symptom and flow rate evaluation. Discussion of treatment options and the nature of the investigation with the patient is recommended before pressure-flow testing is organized.

Filling Cystometry (Cystometrography)

Filling cystometry alone adds limited information to the evaluation of most men with LUTS and is not recommended in routine cases. The test may have value in the evaluation of patients with OAB or known or suspected neurologic lesions and LUTS, but pressure-flow studies provide more specific information.

Urethrocystoscopy

Urethrocystoscopy is not recommended to determine the need for treatment because the linkage between the endoscopic appearance of the lower urinary tract and the treatment outcome is poorly documented and available information suggests that the relationship is minimal (McConnell et al, 1994). The test is recommended for men with LUTS who have a history of microscopic or gross hematuria, urethral stricture disease (or risk factors such as history of urethritis or urethral injury), bladder cancer or suspicion of carcinoma in situ, or prior lower urinary tract surgery (especially prior TURP). Urethrocystoscopy may be considered in men with moderate to severe symptoms who have chosen (or require) surgical or other invasive therapy to help the surgeon determine the most appropriate technical approach.

For example, if urethrocystoscopy reveals a large middle lobe, transurethral incision of the prostate (TUIP) is unlikely to be successful. The decision to perform an open prostatectomy or laser

vaporization may be appropriately influenced by the shape of the gland, as well as its size. Urethrocystoscopy is therefore performed to select (or rule out) specific techniques, not to determine the need for treatment.

Imaging of the Upper Urinary Tract

Upper urinary tract imaging is not recommended in the routine evaluation of men with LUTS unless they also have one or more of the following: hematuria, UTI, renal insufficiency (ultrasound recommended), history of urolithiasis, or history of urinary tract surgery (McConnell et al, 1994; Denis et al, 1998; Kaplan et al, 2006; Abrams et al, 2009). IVU before LUTS or BPH treatment was performed by 73.4% of urologists in the United States in the late 1980s (Holtgrewe et al, 1989). IVU is associated with a 0.1% incidence of significant adverse events. Ultrasound imaging is now preferred but is unnecessary in the uncomplicated case.

The presence or history of hematuria, renal insufficiency, or UTI and/or a history of stones or prior urinary tract surgery increases the likelihood that imaging will demonstrate clinically significant findings (Juul et al, 1989; Andrews et al, 2002). Although there are no conclusive data on the combined incidence of the important clinical predictors just listed, approximately one third of all men with LUTS have one or another indication for urinary tract imaging.

ASSESSING THE EFFECTIVENESS AND SAFETY OF MEDICAL THERAPY FOR LOWER URINARY TRACT SYMPTOMS

The role of treatment for any disease process depends on the magnitude of the clinical effect and the incidence and severity of treatment-related morbidity. Assessing the effectiveness of medical therapies for LUTS requires defining clinically relevant end points, identifying quantitative and reliable clinical outcome measures, eliminating investigator and patient bias, accounting for the placebo response, and enrolling the proper number of patients so that only clinically significant changes are statistically significant. Assessing the safety of medical therapies requires a rigorous effort to identify all treatment-related clinical, biochemical, teratogenic, and mutagenic adverse effects associated with drug treatment.

Clinical End Points

The clinical consequences of BPE or BOO include LUTS and associated reduction of quality of life; detrusor dysfunction characterized by detrusor acontractility, detrusor overactivity, and detrusor fibrosis; incomplete bladder emptying; acute and chronic urinary retention; UTI; renal insufficiency; and hematuria (Shapiro and Lepor, 1995). The goals of treatment include relieving LUTS, decreasing BOO, improving bladder emptying, ameliorating detrusor overactivity, reversing renal insufficiency, and preventing disease progression, which may include a deterioration of symptoms, future episodes of gross hematuria, UTI, AUR, or the need for surgical intervention.

Quantitative Outcome Measures

Symptoms

The primary objective of the AUA Symptom Index or IPSS was to provide a universally accepted instrument to quantify the impact of therapeutic interventions on LUTS (Barry et al, 1992b). There is no standardized format for reporting changes in the AUA symptom score or other quantitative indices of symptom severity after treatment. Symptom response has been reported as a percentage of patients achieving a threshold response or as group mean changes in a symptom score. The literature typically reports the percentage of men achieving a 30% to 50% reduction in the symptom score. Expressing the symptom response as a single threshold response

does not discriminate the overall magnitude of the clinical effect. When the baseline symptom scores are mild to moderate, small and clinically insignificant changes correspond to large percentage changes. When baseline symptom scores are severe, relatively large absolute changes may not be clinically significant. Symptom outcome should be expressed both as a percentage of patients achieving a threshold reduction response and as group mean changes in the symptom score.

The clinical significance of changes in the AUA Symptom Index was reported by [Barry and colleagues \(1995\)](#). A total of 1165 patients participated in a randomized, double-blind, placebo-controlled study of medical therapy and completed the AUA Symptom Index at baseline and after 3 months of treatment. The absolute and percentage changes in AUA Symptom Index and BPH Impact Index were correlated with five global ratings of symptom improvement. The group mean changes in AUA Symptom Index for patients rating their improvement as markedly, moderately, or slightly improved, unchanged, or worse were -8.8 , -5.1 , -3.0 , -0.7 , and $+2.7$, respectively. The relationship between the patients' global ratings of improvement and the AUA Symptom Index and BPH Impact Index changes were dependent on the baseline AUA Symptom Index. This important study provides the data required to determine sample sizes and interpret the clinical significance of symptom improvement in BPH clinical trials. A 3-point change appears perceptible to symptomatic men.

Bladder Outlet Obstruction

Experimental animal models of BOO have demonstrated profound changes in bladder ultrastructure, cellular composition, metabolism, and function resulting from BOO ([Levin et al, 2000](#)). These experimental observations must be cautiously extrapolated to man, because the response to BOO depends on the species and the severity and duration of obstruction. Animal studies demonstrate that under experimental conditions, BOO causes alterations likely to adversely affect bladder function. The justification for measuring and treating BOO in males is to reverse or prevent these deleterious consequences of obstruction.

Because synchronous pressure-flow urodynamic measurements do not correlate with severity of bladder dysfunction, severity of symptoms, or response to therapy, it is difficult to require these studies when evaluating the effectiveness of medical therapy for LUTS. Long-term studies are needed to determine whether urodynamic measurements predict disease progression. At the present time, the primary use of urodynamic testing is to discriminate the differential diagnosis of males presenting with multiple potential causes for LUTS.

Uroflowmetry represents a noninvasive and inexpensive but indirect indicator of urinary performance as a measure of BOO ([Siroky, 1990](#)). The reporting of PFR has been standardized ([Abrams et al, 2003](#)). At the lower spectrum of PFR, a relatively small absolute change (i.e., 4 to 6 mL/sec) corresponds to a relatively high percentage change, whereas at the higher end of PFR, a relatively large absolute change (i.e., 12 to 17 mL/sec) corresponds to a relatively modest percent change. The clinical significance of the changes in PFR cannot be defined, owing to the lack of correlations with relevant clinical, physiologic, or biochemical outcomes.

Bladder Emptying

The clinical significance of a PVR is controversial. [Barry and colleagues \(1993\)](#) reported no correlation between AUA symptom score and PVR. It has been suggested that PVR may predispose to UTI and irreversible bladder dysfunction secondary to stasis and overdistention. **There are no data clearly documenting that the incidence of UTI is related to PVR.** Another limitation of PVR measurements is variability over short intervals of time ([Bruskewitz et al, 1982](#)). It is imperative to measure the PVR on several occasions if this parameter will influence treatment decisions.

There is no standardization for reporting changes in PVR. Typically, the data are presented as absolute group mean changes. The

majority of LUTS and BPH clinical trials exclude patients with high baseline PVR (>300 mL) because of the potential risks of randomization to a placebo or ineffective treatment group. **Therefore, the majority of patients enrolled in clinical trials have clinically insignificant baseline PVR, potentially undermining the relevance of most trials to "real-world" practice.**

Detrusor Overactivity

The definition of detrusor overactivity is the development of a detrusor contraction exceeding 15 cm H₂O at a bladder volume less than 300 mL ([Jepsen and Bruskewitz, 2000](#)). The clinical significance of OAB in men with LUTS or BPH is unresolved. There is no evidence that men with detrusor overactivity electing watchful waiting are predisposed to develop disease progression. The presence of OAB does not reliably predict response to medical or surgical treatment. **Therefore, improvement of OAB is not always a standard outcome measure in clinical trials.**

Urinary Tract Infection, Renal Insufficiency, and Hematuria

Unlike other manifestations of BOO, the diagnosis of UTI, renal insufficiency, and hematuria is not controversial and the requirements for measurement are noninvasive and inexpensive. Because these events are not disease or gender specific, one must be cautious in assuming a causal relationship. There is no convincing evidence that UTI in the aging male population is associated with either a PVR or BOO. It is reasonable to assume that renal insufficiency occurs secondary to urinary retention if renal failure is reversed after catheter drainage. Hematuria may be associated with prostatic vascularity and may sometimes respond to medical therapy with a 5 α -reductase inhibitor.

Because the incidences of UTI, renal insufficiency, and hematuria are relatively uncommon and non-disease-specific events in the aging male population ([McConnell et al, 2003](#)), it would be extremely difficult to design a prospective study to determine whether any LUTS treatment prevents these events in an unselected cohort of men.

Eliminating Bias

Bias may be defined as a systematic error or difference between the true value and that actually attained from all causes other than sampling ability. The only mechanism to ensure that the potential bias of the patient and the investigator does not influence the outcome is a randomized, placebo-controlled, double-blind design. Because patients are typically randomized to receive a drug or its matching placebo, any effect of the investigators' bias would occur equally in the intervention and control groups.

The importance of eliminating bias cannot be overemphasized in clinical trials. Some patients are very enthusiastic about receiving the "new" treatment. In the absence of a blinded randomization, these patients may be disproportionately directed into the active treatment groups. A patient receiving a known placebo would be reluctant to report any adverse events or clinical response. An investigator may be inclined to censor various outcomes if treatment group assignment is known. Although subjective outcome measures such as symptoms are more likely to be influenced by the placebo response, quantitative outcome measurements such as PVR and PFR are also subject to a placebo response, but not prostate volume.

The placebo effect can be substantial in trials of drug treatment of LUTS ([Nickel, 1998](#)). Roehrborn has elegantly written about this effect ([Roehrborn, 1996](#)). **Trials should therefore include a placebo run-in period before recording baseline values;** these baseline values have already incorporated the placebo effect before any comparison is made. Ideally, a 4-week placebo run-in period before initiation of treatment should be included in any trial design.

Similarly, the statistical concept of "regression toward mean" should also be taken into account in trial design. If measuring urinary symptom scores or flow rate measurements, for instance, then in any population there will be some individuals whose values

will be recorded at the extremes of the range for that population. These individuals, when followed up with sequential measurements of the same parameters, will tend to produce values that are less extreme and closer to the mean for the population being studied. Again, incorporating a placebo run-in period will allow this process to occur, at least to a degree, so that subsequent measurements from the baseline values determined after the placebo run-in period are more likely to be in response to a true treatment effect than to these two potentially confounding and misleading processes.

Sample Size

It is a general misconception that the validity of a clinical trial is directly proportional to the number of patients enrolled. One of the objectives of a clinical trial is to determine whether the difference observed between two different treatment groups is clinically relevant. If the sample size of the clinical trial is properly determined in the early planning phase, a statistically significant outcome represents a clinically significant outcome. Calculation of sample size with provisions for adequate levels of significance and power is an essential part of planning a trial. Enrolling an excessive number of patients may result in an overpowered study; that is, a small and clinically insignificant difference may be statistically significant. Conversely, enrolling insufficient numbers of patients may result in an underpowered study; that is, a large and clinically significant difference may not be statistically significant. The larger the number of patients enrolled in a study, the smaller is the change that is required to achieve statistical significance. Therefore, the reader must examine the magnitude of the between-group difference and make a judgment about clinical significance.

Adverse Events

For a drug to enter into clinical investigation in humans, it must be shown to elicit no significant chemical, behavioral, physiologic, teratogenic, mutagenic, or carcinogenic effects in at least two animal models. The typical untoward or adverse events captured in a clinical trial include physical findings, laboratory results, and complaints. A comprehensive physical examination and a battery of general laboratory tests are performed at baseline and at the completion of the trial to capture any untoward events. The patients' complaints are typically captured at each study visit. The adverse clinical effects may be expected or unexpected.

Complaints may be elicited by means of a checklist or by the patients' unsolicited recall of an event. Adverse clinical events are typically greater with a checklist. The assessment of adverse events should determine the frequency and severity of the events and whether an event was severe enough to terminate participation in the study. The majority of clinical trials are powered based on outcome measures and not adverse events. There is a tendency for studies to be underpowered to detect serious adverse events, which may therefore show up only later, in postmarketing surveillance studies.

NONSURGICAL THERAPY FOR BENIGN PROSTATIC HYPERPLASIA

Watchful Waiting or "Self-Help"

A significant proportion of men with LUTS will not choose medical or surgical intervention because the symptoms are not bothersome, the complications of treatment are perceived to be greater than the inconvenience of the symptoms, and there is a reluctance to take a daily pill owing to side effects and/or the cost of treatment. Reassured that the symptoms are not caused by cancer or other serious genitourinary pathology, or that the delay in treatment will not have irreversible consequences, watchful waiting is often the patient-driven treatment of choice in the absence of absolute indications for intervention. Of 670 consecutive men with LUTS or BPH referred to 39 urologists in the Netherlands, 41%

elected watchful waiting (Stoevelaar et al, 1999). It is unreasonable to discourage an informed patient with severe symptoms and no other consequences of LUTS or BPH from pursuing watchful waiting despite the safety and effectiveness of medical therapy. Watchful waiting does not imply the total absence of intervention. The severity and bothersomeness of symptoms may be improved by simple measures such as decreasing total fluid intake especially before bedtime, moderating the intake of alcohol- and caffeine-containing products, and maintaining time-voiding schedules.

The impact of watchful waiting was examined in a study of 556 patients with moderate symptoms of BPH randomized to TURP versus watchful waiting (Wasson et al, 1995). The changes in all outcome measures were significantly greater in the TURP group. A relevant outcome for patients selecting watchful waiting is disease progression. During 3 years of follow-up, treatment failure was observed in 23 (8.2%) and 47 (17%) patients randomized to TURP and watchful waiting, respectively. Treatment failure in the watchful waiting group was most often the result of increasing PVR or symptom score. Significant renal impairment was not seen.

Brown and colleagues (2007) evaluated the effectiveness of self-management as a first-line intervention for men with LUTS in a randomized controlled trial (RCT) set in a teaching hospital and a district general hospital in London. A total of 140 men were randomized between standard care and a self-management program devised from a consensus meeting (Brown et al, 2004) which consisted of three small group sessions of standardized urinary education and lifestyle advice. Self-management significantly reduced the frequency of treatment failure and reduced urinary symptoms. A multicenter RCT of self-management showed that a rigorously structured behavioral program could significantly reduce LUTS severity and decrease objective symptoms such as nocturia, urgency, and frequency compared with standard care alone (Yap and Emberton, 2010). A Chinese study has shown there is additional benefit for self-management advice in men already receiving α -blocker therapy (Chen et al, 2012). Self-management could be considered as first-line treatment for men with LUTS. The self-management program advice given is summarized here (Yap et al, 2009).

Main Components of Self-Management Program for Men with Uncomplicated Lower Urinary Tract Symptoms

Education and Reassurance

- Discuss the causes of LUTS, including normal prostate and bladder function.
- Discuss the natural history of BPH and LUTS, including the expected future symptoms.
- Reassure that no evidence of a detectable prostate cancer has been found.

Fluid Management

- Advise a daily fluid intake of 1500 to 2000 mL (minor adjustments made for climate and activity).
- Avoid inadequate or excessive intake on the basis of a frequency-volume chart.
- Advise fluid restriction when symptoms are most inconvenient (e.g., during long journeys or when out in public).
- Advise evening fluid restriction for nocturia (no fluid for 2 hours before retiring).

Caffeine and Alcohol

- Avoid caffeine by replacing with alternatives (e.g., decaffeinated or caffeine-free drinks).
- Avoid alcohol in the evening if nocturia is bothersome.
- Replace large-volume alcoholic drinks (e.g., pint of beer) with small-volume alcoholic drinks (e.g., wine or spirits).

Concurrent Medication

- Adjust the time when medication with an effect on the urinary system is taken, to improve LUTS at times of greatest inconvenience (e.g., during long journeys and when out in public).
- Replace antihypertensive diuretics with suitable alternatives with fewer urinary effects (via the patient's general practitioner).

Types of Toileting and Bladder Retraining

- Advise men to double-void.
- Advise urethral milking for men with postmicturition dribble.
- Advise bladder retraining. Using distraction techniques (pre-terminated mind exercise, perineal pressure or pelvic floor exercises), aim to increase the minimum time between voids to 3 hours (daytime) and/or the minimum voided volume to between 200 and 400 mL (daytime). The urge to void should be suppressed for 1 minute, then 5 minutes, then 10 minutes, and so on, increasing on a weekly basis. Use frequency-volume charts to monitor progress.

Miscellaneous

- Avoid constipation in men with LUTS.

Patients' and physicians' views on treatment may not always be in agreement. In particular, patients prefer therapies affecting long-term disease progression over those that provide short-term symptom improvement, which contrasts with the beliefs of their physicians. Improved physician-patient communication may help determine best treatment options and may result in better compliance and increased treatment success (Emberton, 2010). The Self-Assessment Goal Achievement (SAGA) questionnaire has been developed to identify treatment goals and assess goal achievement in patients with LUTS and may promote patient-physician interaction and help patients establish realistic treatment goals, which may in turn improve treatment adherence and outcomes (Brubaker et al, 2011).

MEDICAL THERAPY FOR LOWER URINARY TRACT SYMPTOMS AND BENIGN PROSTATIC HYPERPLASIA

Medical therapies extensively investigated for LUTS and BPH include α -adrenergic blockers, 5 α -reductase inhibitors, aromatase inhibitors, and numerous plant extracts. Newer therapies include antimuscarinic drugs, β_3 -agonists, phosphodiesterase inhibitors (PDEIs), and several combinations of these agents. α -Adrenergic blockers and 5 α -reductase inhibitors, and the combination of both of these, are emphasized in this chapter because the safety and efficacy of drugs in these classes have been critically examined, and these drugs are widely prescribed for the treatment of LUTS and BPH. Aromatase inhibitors are briefly reviewed for historical interest. Plant extracts are also reviewed, because these agents are widely used in some parts of the world, despite the lack of properly designed clinical trials. Because plant extracts are not classified as drugs, the marketing and claims are not critically scrutinized by regulatory agencies.

Impact of Medical Therapy

Before the 1980s, prostatectomy was the only widely accepted intervention for LUTS and BPH. The enthusiasm for medical therapy has been supported in part by the limitations of prostatectomy, which include the morbidity of the surgical procedure, failure to invariably achieve a successful outcome, and a small but significant re-treatment rate (Lepor, 1993). Although medical therapies do not achieve the same level of efficacy as prostatectomy, the attractive features of medical therapy relative to prostatectomy are that clinically significant outcomes are obtained with fewer, less serious, and reversible side effects. Because the indication for intervention in the overwhelming majority of patients with LUTS is to improve quality of life by relieving symptoms (Emberton et al, 2008), the lower morbidity of medical therapy is of paramount importance in patient-driven treatment decisions.

In 1990, TURP was second only to cataract surgery in terms of expenditures paid by the U.S. Medicare program. Medical therapy is currently considered the preferred treatment alternative for those individuals who lack absolute indications for surgery. Because the overwhelming majority of men undergoing TURP lack absolute indications for intervention (Mebust et al, 1989) and prefer nonsurgical options (Emberton et al, 2008), the number of prostatectomies performed throughout the world has decreased significantly.

A survey of the U.S. Medicare database also revealed that the absolute number of prostatectomies decreased from 250,000 in 1987 to 116,000 in 1996 to 88,000 in 2000 (Wasson et al, 2000) and has stabilized since then. This 55% reduction in TURP has occurred despite the progressively increasing number of men enrolled in the Medicare program and the overall increase in U.S. spending on BPH (Wei et al, 2005). Similar reductions in TURPs have been reported from France, Canada, Denmark, Germany, and the United Kingdom.

Approximately 30% of American men older than 50 years have moderate to severe symptoms (Chute et al, 1993; Lepor and Machi, 1993). Based on the demographics of the U.S. population, approximately 6.5 to 8.7 million men are eligible to discuss LUTS and BPH treatment options (Jacobsen et al, 1995; Wei et al, 2005). The overwhelming majority of these men would not elect prostatectomy owing to the risks associated with surgical intervention. These individuals are potential candidates for medical therapy.

Selecting Candidates for Medical Therapy

The ideal candidate for medical therapy should have symptoms that are bothersome and negatively affect quality of life so that the patient is willing to make a long-term commitment to medical therapy, providing the drug is effective and adverse experiences are minimal. There are currently no scientific data to support offering medical therapy to individuals with absolute indications for intervention. Individuals with recurrent urinary retention, recurrent UTIs, renal insufficiency, bladder calculi, and recurrent gross hematuria may develop life-threatening consequences from their BOO if it is not managed surgically. Until properly controlled clinical studies unequivocally demonstrate favorable outcomes, patients with absolute indications for intervention should be discouraged from selecting medical therapy. If informed patients are willing to accept potential risks, medical therapy may be offered with a proviso for careful follow-up and future prostatectomy if medical therapy proves ineffective.

Preventing Benign Prostatic Hyperplasia with Medical Therapy

A potential role of medical therapy is to prevent the development of LUTS or BPH or its progression. There are several factors limiting the enthusiasm for preventing the development of LUTS and BPH. The clinical manifestations of LUTS and BPH are rarely life-threatening. Preventative intervention would have to be initiated before the fifth decade of life, coinciding with the development of BPH (Partin, 2000). The long-term exposure to drug-induced adverse events and the prohibitive costs are the primary limitations of prevention therapy. In addition, effective medical and surgical therapy exists when LUTS or BPH ultimately does become clinically evident. Because there are no clinical, biochemical, or genetic predictors of BPH development or progression, every male is potentially at risk. The ability to identify those individuals who are predisposed to develop LUTS or BPH refractory to medical therapy would provide a more compelling rationale for prophylaxis. There is good evidence that men with very large prostates (and usually higher PSA values) are at greater risk for developing urinary retention (Jacobsen et al, 1997) and that medical therapy (finasteride or dutasteride) can significantly decrease this risk of developing urinary retention (McConnell et al, 1998; Roehrborn et al, 2004). The decision to offer preventative therapy for urinary retention depends on the risk of the events, cost associated with treatment, and patient preferences for intervention.

THERAPY WITH α -ADRENERGIC BLOCKERS

Rationale for α -Adrenergic Blockers

The rationale for α -adrenergic blockers in the treatment of LUTS is based on the hypothesis that the pathophysiology of LUTS is in part caused by BOO, which is mediated by α_1 adrenoceptors associated

Figure 104-4. Distribution of α_1 -adrenergic receptors in the lower urinary tract.

with prostatic smooth muscle (Caine et al, 1976, 1978) (Fig. 104-4). The importance of this dynamic obstruction was supported by morphometric studies demonstrating that smooth muscle is one of the dominant cellular constituents of BPH, accounting for 40% of the area density of the hyperplastic prostate (Shapiro et al, 1992). Caine and coworkers reported that the human prostate contracts in the presence of the α -adrenergic agonist norepinephrine. Several investigators subsequently demonstrated that the tension of prostate smooth muscle is mediated by the α_1 adrenoceptor (Hieble et al, 1985; Lepor et al, 1988; Gup et al, 1989). Lepor and coworkers were the first investigators to characterize the α_1 adrenoceptors in the human prostate using radioligand binding studies. These investigators subsequently reported that 98% of the α_1 adrenoceptors are localized to the prostatic stroma (Kobayashi et al, 1994). The importance of the adrenergic innervation of the prostate was further supported by the observation of high levels of norepinephrine in the human prostate (Lepor, 1990). Although the finding of high levels of smooth muscle α_1 adrenoceptors and norepinephrine in the human prostate suggests an important role of the adrenergic innervation in prostatic function, it cannot be assumed that these factors are directly responsible for LUTS. Lepor (1990) reported no significant differences among norepinephrine levels, α_1 adrenoceptor density, and isometric contractile responses to phenylephrine (Gup et al, 1989) in BPH tissues obtained from men with symptomatic and asymptomatic BPH. Other investigators have shown α_1 adrenoceptor levels to be higher in prostatic adenoma relative to prostatic capsule (Yamada et al, 1987; Kawabe et al, 1990). These observations simply show regional differences of α_1 adrenoceptors in the prostate and do not prove that LUTS is caused by upregulation of the α_1 adrenoceptors.

The most definitive evidence that blockade of prostate α_1 adrenoceptors relieves BOO was the observed direct relationship between the area density of prostate smooth muscle and the change in the PFR in 26 patients undergoing prostatic biopsy before initiation of α -blocker therapy with terazosin (Shapiro et al, 1992). Although the prostates of the patients achieving symptom improvement had a significantly greater group mean area density of smooth muscle compared with those of nonresponders, a direct relationship between prostate smooth muscle area density and change in symptom scores was not observed. These observations suggest that nonprostate smooth muscle-mediated α_1 adrenoceptor events may also be responsible for the effectiveness of α blockade and that α_1 -mediated symptom improvement and decreases in BOO are mediated by different mechanisms.

Classification of α -Adrenergic Blockers

α -Adrenergic blockers may be classified according to α adrenoceptor selectivity and serum elimination half-life (Table 104-1).

TABLE 104-1 Classification of α -Adrenergic Blockers and Recommended Doses

CLASS OF α -BLOCKER	DOSE
NONSELECTIVE	
Phenoxybenzamine	10 mg bid
α_1	
Prazosin	2 mg bid
Alfuzosin IR	2.5 mg tid
Indoramin	20 mg bid
LONG-ACTING α_1	
Terazosin	5 or 10 mg qd
Doxazosin	4 or 8 mg qd
Alfuzosin SR	10 mg qd
SUBTYPE SELECTIVE	
Tamsulosin	0.4 mg qd
Silodosin	4-8 mg qd
Naftopidil	25-75 mg/day

bid, twice a day; IR, immediate release; qd, once a day; SR, sustained release; tid, three times a day.

Phenoxybenzamine, a nonselective α -blocker, was shown to be highly effective for LUTS and BPH (Caine et al, 1976, 1978). The limitation of phenoxybenzamine was the high incidence and severity of adverse clinical events. Berthelsen and Pettinger (1977) described two subtypes of the α adrenoceptors (α_1 and α_2). Prazosin was one of the first α_1 adrenoceptor antagonists to be investigated for the treatment of LUTS and BPH (Hedlund et al, 1983). The efficacy of phenoxybenzamine and prazosin is comparable; however, prazosin is better tolerated, implying that efficacy and toxicity are mediated primarily by the α_1 and α_2 adrenoceptors, respectively (Lepor, 1989). Prazosin and other α_1 antagonists, including alfuzosin (Jardin et al, 1991) and indoramin (Ramsay et al, 1985), require at least twice-daily administration owing to the relatively short serum elimination half-lives. The next advance in the development of α -blockers was the development of advanced drugs with serum elimination half-lives that allowed for once-a-day administration. Terazosin (Lepor et al, 1992) and doxazosin (Gillenwater et al, 1995), tamsulosin (Chapple et al, 1997; Narayan and Tewari, 1998; Wilt et al, 2002b), and extended-release (ER) alfuzosin (van Kerrebroeck et al, 2000; McNeill et al, 2005) are long-acting α -blockers that have been shown to be safe and effective for the treatment of LUTS and BPH.

Molecular cloning studies have identified three subtypes of the α_1 adrenoceptors (Andersson et al, 1997). Price and coworkers (1993) reported that the mRNA encoding the α_{1A} adrenoceptors is predominant in the human prostate. The fact that the α_{1A} mRNA is translated does not mean the encoded protein is translated. Lepor and associates reported that with use of autoradiographic (Kobayashi et al, 1994) and immunohistochemical (Walden et al, 1997) techniques, the α_{1A} adrenoceptors and α_{1B} adrenoceptors are predominant in the human stroma and epithelium, respectively. Prostate smooth muscle tension was shown to be mediated by the α_{1A} adrenoceptors (Forray et al, 1994).

Tamsulosin is a once-daily administered α_1 antagonist that exhibits some modest degree of selectivity for the α_{1A} versus the α_{1B} adrenoceptors and no selectivity for the α_{1A} versus the α_{1D} adrenoceptors (Foglar et al, 1995). The pharmaceutical industry has developed α_1 antagonists that are 1000-fold selective for the α_{1A}

adrenoceptors versus α_{1B}/α_{1D} (Forray et al, 1994). Recently silodosin has been introduced. This agent shows 162:1 selectivity for α_{1A} adrenoceptors versus α_{1B} adrenoceptors.

Interpreting the α -Adrenergic Blocker Literature

Meta-analyses derived from the α -blocker literature are often misleading because all of the data for a given drug are combined independent of dose and study design.

Study Designs

Four study designs have been used to investigate α -blockers for LUTS and BPH: titration to fixed dose, titration to response, titration to maximal dose, and randomized dose withdrawal.

Patients enrolled in **titration to fixed dose** studies receive one of several predetermined final doses independent of clinical response unless significant adverse effects are encountered. An advantage of this study design is that dose-dependent efficacy and safety of different doses are determined. A disadvantage is the requirement for a large sample size to identify statistically significant differences between placebo and all of the treatment groups.

Titration to response design allows the investigators to titrate the dose to a threshold response or maximal dose. An advantage of this design is a smaller sample size because all patients receiving active treatment are analyzed as a composite group independent of final dose. A disadvantage of this design is that the maximal therapeutic effect may be underestimated if the titration is not to maximal response. The data are also misleading if expressed in terms of group mean changes according to final dose because all nonresponders are titrated to the maximal dose in the absence of toxicity.

A **randomized dose withdrawal** design begins with an open-label dose titration. All responders are randomized to active drug or placebo. An advantage of this design is the enrichment of responders. A disadvantage is that the results are not generalizable to untreated patients.

A **titration to maximal dose** design, like titration to response, requires a relatively small sample size because there is only one active treatment group. This study design defines maximal clinical response achievable in practice, providing the maximal dose is also the most efficacious tolerable dose.

Dose Response

Multicenter, randomized, placebo-controlled studies have consistently shown that symptom and flow improvement is dependent on the dose of the α_1 -blockers. The differences between the effectiveness of different doses were often not statistically significant because these dose-ranging studies were not adequately powered to show significant differences between dose groups. MacDiarmid and coworkers (1999) have provided the most compelling evidence for a positive correlation relationship between dose and effectiveness of α_1 -blockers in the treatment of LUTS and BPH. Responders to 4 mg of doxazosin were randomized in a double-blind manner to receive 4 mg or 8 mg of doxazosin. The improvement observed in the 8-mg group was 3.7 symptom units greater than in the 4-mg group ($P = .03$). In phase 3 trials, the impact of dose observed in the responders is diluted by the lack of effect in the nonresponders. In clinical practice, nonresponders are withdrawn from treatment.

Review of the Literature

Several reviews have summarized the extensive clinical experiences with α -blockade in LUTS and BPH (Chapple, 1998; Djavan and Marberger, 1999; Lowe, 1999; Lepor et al, 2000; Kaplan, 2008). To date there have been at least 15 systematic reviews of α -blockers in the literature (Yuan et al, 2013), all showing them to be superior to placebo in symptom improvement.

Nonselective and short-acting α_1 antagonists are used less commonly in clinical practice owing to tolerance and the requirement for multiple daily doses. Randomized, double-blind,

placebo-controlled studies have reported the safety and efficacy of phenoxybenzamine (Caine et al, 1978; Abrams et al, 1982), prazosin (Hedlund et al, 1983; Kirby et al, 1987; Le Duc et al, 1990; Ruutu et al, 1991; Chapple et al, 1992), indoramin (Iacovou and Dunn, 1987; Chow et al, 1990; Stott and Abrams, 1991), and IR alfuzosin (Ramsay et al, 1985; Carbin et al, 1991; Jardin et al, 1991; Hansen et al, 1994). With the exception of alfuzosin, these studies typically enrolled relatively small numbers of patients into short-term single-dose studies without quantitative assessment of symptom improvement. Multicenter, randomized, double-blind, placebo-controlled studies have examined the safety and efficacy of the long-acting α -blockers terazosin, doxazosin, tamsulosin, and sustained-release (SR) alfuzosin. In general, patients enrolled in these studies had moderate to severe symptoms, PVR less than 300 mL, and no absolute indications for surgical intervention. Representative studies are reviewed to illustrate the safety, efficacy, and most effective use of α -blockers in LUTS and BPH. The reader is referred to the original articles for more comprehensive outcome assessments.

Terazosin

Randomized, double-blind, multicenter, placebo-controlled studies have consistently demonstrated the efficacy and safety of terazosin for LUTS and BPH (Di Silverio, 1992; Lepor et al, 1992; Lloyd et al, 1992; Brawer et al, 1993; Elhilali et al, 1996; Lepor et al, 1996; Roehrborn et al, 1996) (Table 104-2). The multicenter, double-blind, parallel-group, randomized, placebo-controlled study of once-a-day administration of terazosin to patients with symptomatic LUTS or BPH reported by Lepor and associates (1992) is representative of the expectations of terazosin therapy. Two hundred eighty-five patients entered the double-blind treatment receiving either placebo or 2, 5, or 10 mg of terazosin once daily. Statistically significant decreases from baseline obstructive, irritative, and total symptom scores were observed for all terazosin treatment groups. The levels of improvement in the symptom scores were dose dependent. The levels of improvement in the symptom scores were dose dependent. The 5- and 10-mg terazosin treatment groups exhibited a significantly greater mean decrease in obstructive scores relative to the placebo group (Fig. 104-5).

A statistically significant improvement from baseline was seen in the peak and mean urinary flow rates for all the treatment groups. The effect of terazosin on PFR was also dose dependent. The 10-mg treatment group exhibited a significantly greater increase from baseline in peak and mean urinary flow rates relative to the placebo group. A significantly greater proportion of patients in the 10-mg terazosin treatment group exhibited a greater than 30% improvement in PFR compared with the placebo group. Overall, the adverse events in the four treatment groups were minor and reversible. Although higher incidences of asthenia, flu syndrome, and dizziness were observed in the terazosin treatment groups, the differences from placebo were not statistically significant. There was a significantly greater incidence of postural hypotension in the 5-mg terazosin group than in the placebo group. The incidence of syncope for all terazosin-treated patients was less than 0.5%.

There is legitimate concern regarding whether the results of multicenter studies conducted primarily at tertiary medical centers are generalizable to community practice. Roehrborn and coworkers (1996) reported the results of the Hytrin Community Assessment Trial (HYCAT), which enrolled 2084 men into a 1-year randomized double-blind study comparing the safety and effectiveness of terazosin versus placebo. The overwhelming majority of the patients were enrolled by urologists in community practice, and the daily dose of terazosin was titrated up to 10 mg based on the discretion of the principal investigators. The treatment-related improvements (terazosin minus placebo) in the AUA Symptom Index score and urinary PFR were 1.4 mL/sec and 3.9 symptom units, respectively. The treatment-related incidences of dizziness, asthenia, and peripheral edema were 5.9%, 4.6%, and 3.1%, respectively.

Figure 104-5. Two hundred eighty-five patients were enrolled in a randomized double-blind study comparing placebo (Plb) and 2-mg, 5-mg, and 10-mg terazosin administered once daily. Percentages of patients experiencing more than 30% improvement in total symptom scores and peak urinary flow rates are shown. (From Lepor H. Medical therapy for benign prostatic hyperplasia. *Urology* 1993;42:483–501.)

Kirby (1998) examined the mean changes in blood pressure according to whether patients were normotensive or hypertensive at baseline (Table 104-3). In general, in normotensive men, small, clinically insignificant decreases in blood pressure were noted. Untreated hypertensive men had larger and clinically significant decreases in blood pressure. In men with medically controlled hypertension, terazosin had no clinically significant effect on blood pressure, whereas in men with poorly controlled medically treated hypertension, terazosin significantly lowered blood pressure.

Doxazosin

The half-life of doxazosin is longer than that of terazosin (22 vs. 12 hours). The efficacy, safety, and durability of clinical response of doxazosin has been demonstrated in multicenter, randomized, double-blind, placebo-controlled studies (Chapple et al, 1994; Fawzy et al, 1995; Gillenwater et al, 1995) (Table 104-4) and a

TABLE 104-3 Effect of Terazosin on Blood Pressure in Normotensive and Hypertensive Men

	TREATMENT-RELATED CHANGES IN SYSTOLIC BLOOD PRESSURE/ DIASTOLIC BLOOD PRESSURE (mm Hg)	
	NORMOTENSIVE MEN	HYPERTENSIVE MEN
No antihypertensive treatment	−3.1/−1.7	−13.7/−10.7
Antihypertensive treatment	−2.8/−0.2	−12.6/−11.5

long-term open-label extension study. Fawzy and associates (1995) reported a 16-week multicenter, randomized, double-blind, placebo-controlled titration-to-response study in 100 normotensive patients with LUTS and BPH. Of the 41 evaluable patients receiving doxazosin, 88% underwent titration to the maximal dose (8 mg). The group mean changes in PFR and symptom score were significantly greater in the doxazosin group compared with the placebo group (see Table 104-4). The magnitudes of these treatment-related effects were similar to those of terazosin. The systolic blood pressure changes in normotensive patients were greater than those with terazosin. The treatment-related incidences of dizziness, fatigue, headache, somnolence, hypotension, and nausea were 20%, 8%, 8%, 6%, 8%, and 8%, respectively. The percentages of patients withdrawing because of an adverse event were 14% and 2.1% in the doxazosin and placebo groups, respectively. The treatment-related incidence of adverse clinical events in this doxazosin study appears slightly higher than that of terazosin and may be a result of its greater effect on blood pressure.

Gillenwater and coworkers (1995) reported a multicenter, randomized, double-blind, placebo-controlled titration-to-fixed dose study comparing placebo versus 2, 4, 8, and 12 mg of doxazosin in 248 men with mild-to-moderate essential hypertension. The group mean changes in PFR and Boyarsky symptom score are summarized in Table 104-4 according to treatment groups. Because relatively small numbers of patients were randomized into the individual treatment groups, the failure to demonstrate statistical significance between placebo and some of the active treatment groups reflects the small sample size. The group mean improvement in PFR was dose dependent and statistically significant relative to placebo for all active treatment groups. The mean improvements in symptom scores relative to placebo for the group were statistically significant for the 4- and 8-mg doxazosin groups. Statistically and clinically significant changes in systolic blood pressure were observed between

NR, not reported; PFR, peak flow rate.

the placebo and the 4-, 8-, and 12-mg doxazosin groups. Lowering of blood pressure was a desirable outcome in these hypertensive patients. The overall treatment-related incidences of dizziness and fatigue were 15% and 10%, respectively. The percentages of patients withdrawing because of an adverse event in the doxazosin versus placebo groups were 11.1% and 4.1%, respectively. **Statistically significant changes in symptom scores and PFR relative to baseline have been reported in a long-term open-label doxazosin extension study (Lepor, 1995).** The initial improvements in symptom scores and PFR in 450 patients were maintained for up to 42 months. Kirby (1995) summarized the effects of doxazosin on blood pressure in normotensive and hypertensive men enrolled into two double-blind, placebo-controlled trials (Fawzy et al, 1995; Gillenwater et al, 1995). The treatment-related group mean reductions in sitting systolic blood pressure in the normotensive and hypertensive patients were 3 and 17 mm Hg, respectively. The treatment-related group mean reductions in sitting diastolic blood pressure in the normotensive and hypertensive patients were 4 and 3 mm Hg, respectively.

The controlled-release gastrointestinal therapeutic system (GITS) formulation of doxazosin reduces the plasma peak-to-trough ratio to minimize the need for titration. To compare the two formulations in 795 men with LUTS or BPH, doxazosin standard was initiated at 1 mg/day, titrated to 2 mg/day after 1 week, to 4 mg/day at 3 weeks, and to 8 mg/day at 7 weeks if indicated. This regimen was compared with doxazosin GITS initiated at 4 mg once daily and titrated to 8 mg once daily after 7 weeks if indicated, and to a placebo group over 13 weeks. The symptoms of LUTS were measured with the IPSS, which has seven questions (covering frequency, nocturia, weak urinary stream, hesitancy, intermittence, incomplete emptying, and urgency) scored 0 (absent) to 5 (severe). On the IPSS, there was an improvement of -8.4 and -8.0 with doxazosin standard and GITS, respectively, compared with -6.0 in the placebo group. Doxazosin standard and GITS produced clinically comparable increases in mean peak urinary flow rate, compared with placebo, with a greater improvement observed earlier after treatment with doxazosin GITS than with the doxazosin standard. A similar number of patients in both doxazosin groups were titrated to the maximum dose of 8 mg for both formulations. The incidence of adverse effects was slightly higher with doxazosin standard than doxazosin GITS and placebo, which caused a similar incidence.

The aforementioned study and another with 680 men were combined to further analyze the comparison between doxazosin standard and GITS (Kirby et al, 2003). In addition to confirmation of the results given earlier, a subgroup reporting sexual dysfunction at baseline had a modest clinical improvement in sexual function with both preparations of doxazosin. Treatment-related adverse events occurred in 16.1% of patients on doxazosin GITS, 25.3% of patients on doxazosin standard, and 7.7% of placebo patients. Headache

and dizziness occurred in 6.0% and 5.3% of doxazosin GITS patients compared with 5.1% and 9.1% of doxazosin standard patients, respectively (placebo, 4.5% and 1.9%, respectively). Fewer patients on doxazosin GITS (5.7%) or placebo (2.6%) discontinued treatment because of adverse events than on doxazosin standard (7.2%). The reduction in blood pressure was not clinically significant in the normotensive patients, but there were clinically significant reductions in blood pressure with both preparations of doxazosin. A comparison of the nonconcurrent multicenter, randomized, double-blind, placebo-controlled studies of terazosin (see Table 104-2) and doxazosin (see Table 104-4) shows similar efficacy. Studies of doxazosin versus tamsulosin (Kirby et al, 2003) and doxazosin versus alfuzosin (de Reijke et al, 2004) revealed only minor differences in safety and efficacy.

α -Blockers such as doxazosin may influence smooth muscle growth in the prostate. In BPH patients treated with α_1 -adrenoceptor antagonists, there is a decreased expression of myosin heavy chain mRNA, a functional marker for the smooth muscle phenotype (Lin et al, 2001).

Biopsy and prostatectomy specimens from untreated and doxazosin-treated BPH patients suggest that doxazosin may induce apoptosis in both the epithelial and stromal cells with little effect on cell proliferation. The apoptosis was associated with a decrease in α -smooth muscle actin expression and stromal regression. Another study showed that the mean pretreatment baseline apoptosis was 1.9% and 1.0% for the epithelial and stromal prostate components. The mean apoptotic indexes increased after 3 months of doxazosin treatment for BPH to 6% in the glandular epithelial and 12% in the smooth muscle cells. By 12 months after treatment, epithelial apoptosis had decreased to constitutive levels, whereas the apoptotic index of prostatic stromal cells remained high (Kyprianou et al, 1998).

In primary cultures of human prostate stroma cells, doxazosin increased apoptosis and decreased cell numbers. Transforming growth factor- β 1 (TGF- β 1) also decreased cell numbers, and because doxazosin increased the levels of TGF- β 1 in the cells, it was suggested that the effect of doxazosin may be mediated through TGF- β 1 (Ilio et al, 2001).

The ability of doxazosin to induce apoptosis may be shared with the other quinazoline-based α_1 -adrenoceptor antagonists terazosin and prazosin, although it seems unlikely that this effect is α_1 -adrenoceptor mediated (Gonzalez-Juanatey et al, 2003). The apoptotic effects of the quinazoline-based α_1 -adrenoceptor antagonists may be linked to their ability to inhibit hERG potassium channels, which has been demonstrated using cloned channels expressed in *Xenopus* oocytes (Thomas et al, 2004).

Recent data also suggest that doxazosin may have a mildly beneficial impact on sexual function in men with LUTS and BPH (Kirby et al, 2005). The mechanism for this effect is uncertain but may be the result of a vasodilatory action within the corpora cavernosa.

Tamsulosin

Tamsulosin is currently the most widely used α_1 antagonist investigated for LUTS and BPH (Foglar et al, 1995). One of the features of tamsulosin is that it exhibits some degree of specificity for the α_{1A} adrenoceptors (Foglar et al, 1995). The efficacy and safety of tamsulosin has been investigated in four multicenter, randomized, double-blind, placebo-controlled studies (Kawabe et al, 1990; Abrams et al, 1995; Lepor, 1998; Narayan et al, 1998) (Table 104-5).

Lepor (1998) and coworkers reported a multicenter, randomized, double-blind, placebo-controlled study of 756 American men with clinical LUTS and BPH randomized to receive placebo or 0.4 or 0.8 mg of tamsulosin for 13 weeks. The mean changes in AUA symptom score, PFR, and adverse events are summarized in Table 104-5. The symptom score improvements were significantly greater in the 0.8-mg tamsulosin group compared with the 0.4-mg group. The treatment-related incidences of dizziness, asthenia, rhinitis, and abnormal ejaculation in the 0.4-mg group were 5%, 3%, 3%, and 6%, respectively, and in the 0.8-mg group they were 6%, 3%, 9%, and 18%, respectively. The mean changes in systolic and diastolic blood pressure in the placebo and tamsulosin groups were not significantly different for both hypertensive and normotensive patients. In the patients who were hypertensive and uncontrolled, the systolic blood pressure changes in the placebo, 0.4-mg, and 0.8-mg groups were -8.4, -7.2, and -10.2 mm Hg, respectively.

Of the 618 patients who completed the 13-week randomized study reported by Lepor (1998) and coworkers, 418 (68%) continued into the 40-week extension study on the same double-blind medication and dose. The symptom and flow rate improvements observed at the end of the 13-week study were maintained throughout the 40-week extension study.

Narayan and associates (1998) reported the results of a randomized, double-blind, placebo-controlled trial comparing the safety and effectiveness of 0.4 and 0.8 mg of tamsulosin versus placebo. Seven hundred thirty-five men were randomized in the study. The active treatment was 13 weeks. The treatment-related improvements in the AUA symptom score and PFR were comparable with those reported by Lepor (1998) and coworkers. The differences between 0.4 mg and 0.8 mg were not statistically significant; however, the study lacked statistical power to show clinically significant differences between the active treatment groups. The treatment-related incidences of asthenia, dizziness, rhinitis, and abnormal ejaculation observed for the 0.4-mg tamsulosin group were 2%, 5%, 3%, and 11%, respectively. The incidences of retrograde ejaculation and rhinitis were significantly greater in the 0.8-mg group compared with the 0.4-mg group. No statistically or clinically significant differences were observed for systolic blood pressure between any of the treatment groups.

A systematic review of tamsulosin therapy for LUTS/BPH has been published (Wilt et al, 2002b). This included 14 studies with a total of 4122 patients. The mean change in symptom score was 12% for the 0.4-mg dose and 16% with the 0.8-mg dose. Improvements in flow rate were 1.1 mL/sec for both doses. In general, adverse events were mild and included dizziness, rhinitis, and abnormal ejaculation. These increased in a dose-dependent manner, with discontinuations resulting from such effects similar to placebo at 0.2 mg but increasing to 16% with the 0.8-mg/day dose.

Alfuzosin

Jardin and colleagues (1991) reported the first large-scale, multicenter, randomized, placebo-controlled trial demonstrating that alfuzosin was safe and effective for the treatment of LUTS and BPH (Table 104-6). A long-term open-label extension study showed that the effectiveness of alfuzosin was durable up to 30 months (Jardin et al, 1994). The primary limitation of alfuzosin was a requirement for multiple daily doses (2.5 mg three times a day or 5 mg twice a day). In the absence of any demonstrable advantage over the once-a-day drugs such as terazosin, doxazosin, and tamsulosin, there was no compelling reason to prescribe alfuzosin.

ER or SR alfuzosin is a new formulation that allows for a once-daily dosing regimen without dose titration. Buzelin and coworkers (1997a, 1997b) reported the first randomized, multicenter, placebo-controlled trial evaluating the safety and effectiveness of SR alfuzosin for the treatment of LUTS and BPH. Three hundred and ninety patients were randomized to once-daily 5 mg alfuzosin versus placebo for 12 weeks. The treatment-related improvements in the IPSS and PFR were -1.6 symptom units and 1.3 mL/sec, respectively. The incidences of dropouts because of adverse events were 4.6% and 7.1% in the SR alfuzosin and placebo groups, respectively. The 2-mm Hg change in systolic and diastolic blood pressure was not significantly different from that in the placebo group. The incidences of dizziness and asthenia were similar in the SR alfuzosin and placebo groups.

SR alfuzosin (10 mg once a day) has been compared with IR alfuzosin (2.5 mg three times daily) and placebo (van Kerrebroeck et al, 2000). After a 1-month placebo lead-in, 447 patients were randomly assigned in equal proportions to the three treatment groups for 3 months. The improvements in the IPSS were 6.9, 6.4, and 4.9 in the alfuzosin 10 mg/day, alfuzosin 2.5 mg three times a day, and placebo groups, respectively. The symptom improvement observed in both active treatment groups was significantly greater than that in the placebo group. The improvements in the filling and voiding subscores and quality-of-life index were also significantly greater in the active treatment group relative to the placebo group. The improvements in the PFR were 2.3 mL/sec, 3.2 mL/sec, and 1.4 mL/sec in the SR alfuzosin, IR alfuzosin, and placebo groups,

TABLE 104-6 Efficacy of Alfuzosin in Benign Prostatic Hyperplasia

* $P < .05$.† $P < .001$.‡ $P < .01$.

PFR, peak flow rate.

respectively. The modest improvements in the PFR were significantly greater in both active treatment groups compared with placebo. The incidences of dizziness were 2.1%, 4.7%, and 1.3% and of asthenia were 3.5%, 0.7%, and 2.6% in the SR alfuzosin, IR alfuzosin, and placebo groups, respectively. No sexual dysfunction was reported in the 10-mg/day alfuzosin group. There were no statistically or clinically significant treatment-related effects on blood pressure in normotensive or hypertensive patients. Of those men who were hypertensive at baseline, the mean reductions in the standing blood pressure were 8.1, 8.6, and 5.8 mm Hg, respectively, in the SR alfuzosin, IR alfuzosin, and placebo groups.

In an open extension of the ALFORTI trial there was a 35% improvement from baseline in quality of life (van Kerrebroeck et al, 2000). Some part of this effect may be the result of a mildly beneficial impact on sexual function (van Moorselaar et al, 2005).

Because of the lack of adverse effects and blood pressure changes, alfuzosin has been described as a uroselective drug (Kirby, 1998). SR alfuzosin exhibits no pharmacologic uroselectivity for any of the α_1 subtypes (Andersson et al, 1997). In vivo studies in the conscious rat have shown that alfuzosin reduces urethral pressure without significantly altering blood pressure (Martin et al, 1995). This experimental observation does not prove clinical uroselectivity because terazosin and doxazosin do not alter blood pressure in normotensive patients. Another explanation for the lack of adverse events has been the low penetration of alfuzosin into the brain (Rouquier et al, 1994).

The long-term effectiveness of IR alfuzosin 2.5 mg three times a day is supported by an open-label prospective 3-year trial involving 3228 men with LUTS or BPH (Lukacs et al, 2000). The improvements in symptom score in BPH-specific health-related quality-of-life index observed at the 3-month visit were maintained throughout the 36 months of follow-up. A total of 20.1% of the men withdrew from the study. Only 4.2% of the men discontinued therapy because of an adverse event. Only 0.3% of men experienced AUR.

Silodosin

In Japan, silodosin, a selective α_1 -adrenergic receptor antagonist, is the LUTS-BPH market leader and received FDA approval in October 2008 (Watson Pharmaceuticals, Parsippany, NJ). In two phase 3 studies, 8-mg once-daily silodosin taken for 12 weeks resulted in significant and rapid improvement of IPSS compared with placebo. Silodosin was shown to increase urine flow in 2 to 6 hours after the initial dose. Improvement of symptoms was realized in 3 to 4 days, with the majority of patients, including men on concomitant cardiovascular medications, achieving at least a three-point improvement in IPSS score, regardless of age or severity of symptoms. It was associated with a low incidence of orthostatic hypotension and syncope, fainting, and dizziness (Marks et al, 2009). As the newest agent available, silodosin has had to satisfy more rigorous cardiovascular requirements from the FDA than other, older agents. Silodosin demonstrated minimal effects on the cardiovascular system, without any meaningful prolongation of the QT interval. The most

common drug-related side effect was retrograde ejaculation (better described as anejaculation). Rates of discontinuation of therapy because of retrograde ejaculation were low. The second most commonly reported adverse event was dizziness, the rate of which was only slightly higher than in placebo-treated patients. There were no reported events of symptomatic orthostatic hypotension or dizziness when administered with a single dose of medication for erectile dysfunction (ED) in healthy men.

A randomized, double-blind, placebo-controlled study comparing silodosin with tamsulosin or placebo was conducted at 88 centers in Japan (Kawabe et al, 2006). Men aged 50 years or older with an IPSS of 8 or higher, a quality-of-life score of 3 or more, a PFR of less than 15 mL/sec, a prostate volume of 20 mL or more, and a PVR urine volume of less than 100 mL were eligible for enrollment. Patients were randomized to receive silodosin 4 mg twice daily, tamsulosin 0.2 mg once daily (i.e., a lower dose than used in the United States or Europe), or placebo, for 12 weeks; 457 men were randomized (silodosin, 176; tamsulosin, 192; and placebo, 89). Changes in the total IPSS from baseline in the silodosin, tamsulosin, and placebo groups were -8.3, -6.8, and -5.3, respectively. There was a significant decrease in the IPSS versus placebo in the silodosin group from 1 week. In the early-stage comparison, silodosin showed a significant decrease in IPSS versus tamsulosin at 2 weeks. Changes in quality of life from baseline were -1.7, -1.4, and -1.1 in the silodosin, tamsulosin, and placebo groups, respectively. Silodosin showed a significant improvement in quality-of-life score versus placebo. In the subgroup of patients with severe symptoms (IPSS ≥ 20), silodosin also gave a significantly better improvement than placebo (-12.4 vs. -8.7). The incidence rates of adverse events and drug-related adverse events were, respectively, 88.6%, 82.3%, and 71.6% and 69.7%, 47.4%, and 36.4%, respectively. The most common adverse event in the silodosin group was abnormal ejaculation, which occurred more often in the silodosin than in the tamsulosin group (22.3% vs. 1.6%). However, only five men (2.8%) discontinued treatment for abnormal ejaculation. It is unclear how men in other populations will respond to this effect. Measurement by Noguchi and colleagues (2008) of intraurethral pressure in the prostatic urethra and intraluminal pressure in the vas deferens in anesthetized male dogs given the α_1 -adrenoceptor agonist phenylephrine and then a series of α_1 -adrenoceptor antagonists showed that silodosin had the highest selectivity for the vas deferens (7.5-fold), followed by naftopidil (4.3-fold), alfuzosin (3.8-fold), tamsulosin (2.6-fold), and prazosin (2.5-fold). These results suggest that high tissue selectivity for the vas deferens over the urethra may contribute to the incidence of abnormal ejaculation.

A recent meta-analysis of silodosin included four RCTs with a total of 2504 patients and suggested that silodosin is an effective therapy for LUTS in men and is not inferior to 0.2-mg tamsulosin (Ding et al, 2013). In addition, a recent review suggests that silodosin is a rapidly efficacious and safe agent in the treatment of LUTS or BPH in men. A lack of clinically important cardiovascular side effects makes it of potential use in the elderly. The higher risk of ejaculatory dysfunction may make it unsuitable for younger men (Osman et al, 2012). In a urodynamic study of 57 patients,

the storage phase of the pressure flow study showed that the bladder capacity at first desire to void increased significantly, the number of patients with UDCs reduced, and mean detrusor pressure at maximum flow significantly decreased from 72.5 to 51.4 cm H₂O, after 4 weeks' treatment with 8 mg silodosin. The mean Bladder Outlet Obstruction Index score decreased significantly from 60.6 to 33.8 (Matsukawa et al, 2009).

Naftopidil

Naftopidil, a relative α_{1D} -adrenoceptor-selective antagonist, seems more effective for patients showing a dominant expression of the α_1 -adrenoceptor subtype. The α_1 -adrenoceptor antagonists tamsulosin hydrochloride and naftopidil were administered to 96 patients with LUTS or BPH for 8 weeks in a crossover study. With the administration of both drugs, the IPSS significantly decreased and the maximum urinary flow significantly increased. Whereas Naftopidil monotherapy decreased the IPSS for storage symptoms, tamsulosin monotherapy decreased the IPSS for voiding symptoms (Ikemoto et al, 2003). It has been suggested that its preference for the α_1 -adrenoceptor subtype may give naftopidil benefits for the storage symptom component of LUTS. A Cochrane systematic review found relatively few published data on naftopidil (Garimella et al, 2009), although a recent patient preference study showed no substantial differences between it and silodosin (Masuda et al, 2012).

Effects of α -Adrenergic Blockers on Bladder Outlet Obstruction

The primary objective of medical therapy is to improve urinary symptoms. The relevance of urodynamic studies for assessing the clinical use of medical therapy for LUTS is controversial. A drug that improves urodynamic parameters of BOO without relieving LUTS would be of limited clinical usefulness. Conversely, a drug that relieves LUTS without improving urodynamic parameters of BOO would still be of great clinical importance. There are relatively few randomized, placebo-controlled studies examining the effects of α -blockers on pressure-flow parameters. One of the limitations to designing these urodynamic studies is the definition of a clinically significant outcome.

Martorana and colleagues (1997) reported a randomized, double-blind, placebo-controlled study examining the effect of 1 month of alfuzosin, 2.5 mg three times a day, on pressure-flow urodynamic parameters. The changes in detrusor pressure at maximum flow, detrusor opening pressure, and maximum detrusor pressure were significantly greater in the alfuzosin treatment group compared with the placebo group. There were no significant differences between the effects of alfuzosin and those of placebo on PFR.

α -Blockers and Sexual Function and Sexual Side Effects

Sexual function is complex and includes multiple domains such as sexual desire (libido), erectile function, and ejaculatory function. Erectile and ejaculatory functions are frequently reduced in patients with LUTS and can affect their quality of life. Therefore the treatment of LUTS should aim to maintain or even restore sexual function. α_1 -Adrenoceptor antagonists lack major effects on sexual desire in placebo-controlled studies (van Dijk et al, 2006). Reports on erectile function are inconsistent, with both beneficial and adverse effects being reported, but ED can occur in some patients without clear differences among drugs. Ejaculatory dysfunction during treatment may represent (relative) anejaculation. It occurs more frequently with tamsulosin and even more so with silodosin (see earlier) than with other drugs of this class.

α -Adrenergic Blockers in the Elderly

The adverse events associated with terazosin and doxazosin that may be particularly problematic in the elderly are dizziness and orthostatic hypertension. Kaplan and colleagues (1997) reviewed a personal series of 36 men with LUTS or BPH older than 80 years

treated with terazosin or doxazosin. α -Adrenergic blockers were well tolerated, and no serious adverse events were observed. This experience was not of adequate size to address the incidence of falls. Pooled analysis of multicenter, randomized, placebo-controlled studies of terazosin (Zhang and Manski, 1998), doxazosin (Kaplan and D'Alisera, 1998), and tamsulosin (Chapple et al, 1997) has revealed that the incidences of adverse events are not age dependent. It is important to emphasize that men enrolled into these studies were highly selected and so the tolerability and safety findings are not generalizable to all elderly men.

Data from population studies such as the 5872-participant Osteoporotic Fractures in Men study and a population-based case-control study using data from a managed care organization in Southern California with more than 3 million members suggest that moderate and severe LUTS independently increase the 1-year risk of falls, particularly recurrent falls, in community-dwelling older men (Parsons et al, 2009) and that there is a modest increase in risk of hip fractures associated with exposure to α -blockers, which requires further investigation (Jacobsen et al, 2008).

Formal clinical trials of tamsulosin observed a 12% incidence of orthostatic hypotension in patients taking 0.4 mg tamsulosin, and a 6% incidence in patients taking placebo 4 to 8 hours after administration, but without urgent treatment being required (U.S. Food and Drug Administration, 1997).

Bird and associates (2013) looked at U.S. health care claims data for men aged 40 to 85 years who were first prescribed tamsulosin or a 5 α -reductase inhibitor between January 2001 and June 2011 and who developed hypotension requiring hospital admission. These researchers observed an increased rate ratio for severe hypotension with tamsulosin treatment (42.4 events per 10,000 person-years) versus 5 α -reductase inhibitor treatment (31.3 events per 10,000 person-years). The greatest increase in risk varied in magnitude from 151% to 256% and was observed during the first 8 weeks of new drug use and the first 8 weeks after restarting drug treatment, suggesting a first-dose phenomenon similar to that occurring with nonselective α antagonists. This suggests that physicians should warn patients regarding a first-dose phenomenon with tamsulosin. A smaller increase in risk for hypotension, varying from 19% to 36%, persisted during maintenance tamsulosin treatment. A recent Cochrane review also found higher rates of dizziness with larger tamsulosin doses (0.8 mg, 17% dizziness; 0.4 mg, 9%; 0.2 mg, 3%), suggesting a dose-dependent effect (Wilt et al, 2002b).

α -Adrenergic Blockers and the Treatment of Lower Urinary Tract Symptoms and Coexisting Hypertension

Approximately 30% of men treated for LUTS or BPH have coexisting hypertension (Boyle and Napalkov, 1995). The α -blockers terazosin and doxazosin are established agents for the treatment of hypertension. The overwhelming clinical evidence demonstrates that terazosin and doxazosin lower blood pressure primarily in hypertensive men and that the blood pressure lowering is clinically significant (Fawzy et al, 1995; Gillenwater et al, 1995; Kirby, 1995; Lepor et al, 1997; Kirby, 1998; Lowe et al, 1999).

An interim analysis of the Anti-Hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) undermined the use of doxazosin in men at risk for developing congestive heart failure (ALLHAT Collaborative Research Group, 2000). In this study of 24,335 patients with hypertension and at least one other coronary risk factor, men were randomized to chlorthalidone, doxazosin, amlodipine, or lisinopril. A significant increased risk of congestive heart failure in the doxazosin group relative to the chlorthalidone group was the basis for the decision to discontinue the doxazosin arm of the antihypertensive trial. There was no significant increase in congestive heart failure between doxazosin and the other antihypertensive agents. Comparable levels of blood pressure reduction were achieved by both drugs. The ALLHAT study questions the role of doxazosin as first-line therapy for the treatment of hypertension. The study does not assess the relative risks and benefits of doxazosin in men with BPH and hypertension, nor does it have any bearing on the use of doxazosin

in combination with other antihypertensive agents. Doxazosin remains an acceptable agent to treat LUTS that coexists with hypertension. It should be at the discretion of the physician managing the hypertension to add additional agents for treating the hypertension. It is interesting to note that a current first-choice antihypertensive agent, carvedilol, with both β -blocker and potent and selective α_1 -adrenoceptor blockade effects has recently been shown to have a positive benefit for men with hypertension and LUTS or BPH (Lewandowski et al, 2013).

Mechanism of Adverse Events Associated with α -Adrenergic Blockade

Dizziness and asthenia are the adverse events most commonly associated with α -blocker therapy. Elucidating the mechanism of action for these adverse events is essential for α_1 subtype drug development programs. It has been assumed that dizziness and possibly asthenia were caused by cardiovascular effects. Lepor and colleagues (2000) correlated the incidence of adverse events associated with terazosin relative to blood pressure changes. Men experiencing dizziness and asthenia did not exhibit greater changes in blood pressure while on terazosin therapy. Only postural hypotension was associated with greater changes in blood pressure. α_1 -Adrenergic-mediated dizziness and asthenia are likely the result of effects at the level of the central nervous system (CNS). Therefore, it cannot be assumed that developing an α -blocker that eliminates effects on blood pressure will significantly improve the tolerability of α -blockers.

α -Blockers and Intraoperative Floppy Iris Syndrome

Intraoperative floppy iris syndrome (IFIS) complicates approximately 2% of cataract surgery cases. The clinical manifestations of IFIS are poor preoperative pupil dilation, iris billowing and prolapse, and progressive intraoperative miosis. Surgical complications are increased when IFIS is not anticipated or recognized by the surgeon. Since IFIS was first described in 2005 (Chang et al, 2005), its association with the α_1 -adrenergic antagonist tamsulosin has become well established. It appears that α_{1A} is the predominant receptor subtype in the iris dilator muscle, as well. The persistence of IFIS long after the discontinuation of tamsulosin suggests a semi-permanent muscular atrophy and loss of tone. It is not clear how long one must take tamsulosin before experiencing these chronic muscular changes. Anecdotal reports suggest that IFIS does not occur until patients have been on tamsulosin therapy for approximately 4 to 6 months. IFIS can also occur up to several years after discontinuation of tamsulosin. IFIS has also been reported but less commonly with non-subtype-specific α_1 -adrenergic antagonists, such as terazosin, doxazosin, and alfuzosin. According to an online survey, 95% of members of the American Society of Cataract and Refractive Surgery believe that tamsulosin made cataract surgery more difficult, and 77% believed it increased the risks of surgery (Chang et al, 2008).

Being able to elicit a prior history of tamsulosin use now enables cataract surgeons to anticipate IFIS and to use alternative methods of managing the complication. Prevention of IFIS by withdrawing tamsulosin preoperatively has not shown consistent benefit. Therefore, in a patient with a known diagnosis of cataract, prescribing physicians may wish to consider involving the patient's cataract surgeon before initiating tamsulosin or α -blocker treatment. Patients should also be encouraged to report any prior or current history of α_1 -antagonist use to their ophthalmic surgeon before undergoing any eye surgery. Intraoperative sub-Tenon lidocaine reduces significantly the incidence of IFIS in patients taking oral α -adrenergic inhibitors (Klysiak and Korzycka, 2014).

Comparison of α -Adrenergic Blockers

Because the therapeutic effect and adverse events associated with α -blockers are both dose dependent, the effectiveness and tolerability of two different α -blockers can be determined only in a

randomized, double-blind, placebo-controlled trial. It is imperative that these studies be appropriately powered to show statistically significant effects for effectiveness and tolerability.

Buzelin and coworkers (1997a) reported a randomized, placebo-controlled study comparing α -blockers (IR alfuzosin, 2.5 mg three times a day, versus tamsulosin, 0.4 mg/day). The improvements in Boyarsky symptom score and PFR and the incidences of dizziness and asthenia were not significantly different between the two treatment groups. The effects of alfuzosin and tamsulosin on systolic and diastolic supine or standing blood pressures in the hypertensive patients were also not significantly different. This study suggests that IR alfuzosin and tamsulosin have equivalent effectiveness and tolerability. The obvious benefit of tamsulosin is that the dose does not have to be titrated.

The recommended daily doses of terazosin, doxazosin, tamsulosin, and SR alfuzosin are 10 mg, 8 mg, 0.4 mg, and 10 mg, respectively. The clinical data suggest that terazosin, 10 mg, and doxazosin, 8 mg, are more effective than tamsulosin, 0.4 mg, and alfuzosin, 10 mg (see Tables 104-2, 104-4, 104-5, and 104-6) but the incidences of asthenia and dizziness appear to be higher for terazosin and doxazosin. **The apparent better tolerability of tamsulosin and SR alfuzosin may simply be because of degree of α_1 -blockade, and not uroselectivity.** Assessing the relative efficacy and tolerability of daily terazosin, 10 mg, or doxazosin, 8 mg, versus tamsulosin, 0.4 mg, or SR alfuzosin, 10 mg, would address this issue. In the absence of these studies, nonconcurrent studies can be compared, recognizing the potential impact of differences in study design, patient selection, recording of adverse events, and administration.

Terazosin and doxazosin exhibit very similar pharmacologic and pharmacokinetic properties. It is therefore not surprising that the effectiveness and tolerability of these two agents are also comparable. The effectiveness of terazosin and doxazosin are both dose dependent, with the greatest recorded improvements in symptom scores observed at the 10-mg and 8-mg daily doses, respectively. These doses have both been shown to be significantly more effective than lower doses. Although the incidence of adverse events is dose dependent, the 10-mg and 8-mg doses of terazosin and doxazosin are, in general, well tolerated.

Terazosin is unit priced so that there is no financial disincentive to titrate up to the 10-mg dose. There is no significant cost advantage between 10 mg of terazosin and 8 mg of doxazosin. **Thus, until data from randomized, double-blind comparative trials demonstrate the contrary, 10 mg of terazosin and 8 mg of doxazosin should be considered equivalent.**

Tamsulosin and SR alfuzosin have been positioned as uroselective α_1 -blockers. Randomized studies have shown that 0.8 mg of tamsulosin is significantly more effective at relieving symptoms than the 0.4-mg dose (Lepor, 1998). No dose-ranging studies have been performed with SR alfuzosin. Unfortunately, an 0.8-mg tamsulosin dose has not been manufactured. Whereas the 0.8-mg tamsulosin dose appears to result in less asthenia than terazosin and doxazosin, the incidence of dizziness is comparable and the incidences of rhinitis and abnormal ejaculation are markedly greater. **Tamsulosin, 0.4 mg, is the most appropriate dose owing to the cost and adverse events associated with the 0.8-mg dose.** The advantage of 0.4 mg of tamsulosin is that this clinically effective dose can be administered without dose titration.

The major advantage of 0.4 mg of tamsulosin and SR alfuzosin is the lack of requirement for dose titration. For men with urinary retention, tamsulosin and SR alfuzosin will likely decrease the time to voiding trial because of the lack of titration to an effective dose. The data suggest that tamsulosin and SR alfuzosin exhibit less effect on blood pressure in hypertensive men compared with terazosin and doxazosin.

Summary

Multicenter, randomized, double-blind, placebo-controlled studies have unequivocally demonstrated the safety and efficacy of α -blockers for the treatment of LUTS. The clinical response is rapid and dose dependent. Long-term open-label studies have

demonstrated that the clinical response is durable. The long-acting α_1 -blockers are well tolerated. The α_1 -blockers are safe in the elderly (once first-dose effects are guarded against) and diminish LUTS. The effect on risk of falling and fractures needs further investigation. Terazosin and doxazosin significantly lower blood pressure only in hypertensive patients. Direct comparison studies of the α -blockers are sparse and involve small numbers of patients, and therefore any claims of superiority cannot be justified.

ANDROGEN MANIPULATION

Rationale for Androgen Manipulation

The rationale for androgen suppression is based on the observation that the embryonic development of the prostate is dependent on the androgen dihydrotestosterone (DHT) (Shapiro, 1990). Testosterone is converted to DHT by the enzyme 5 α -reductase. The genetic deficiency of 5 α -reductase in males results in a rudimentary prostate and in feminized external genitalia (Walsh et al, 1974). The development of BPH is also an androgen-dependent process (Coffey and Walsh, 1990). Castration and pharmacologic agents suppressing testosterone and DHT synthesis or action have been shown to reduce prostate volume in men with established LUTS or BPH (McConnell, 1990). Peters and Walsh (1987) demonstrated that androgen suppression causes regression primarily of the epithelial elements of the prostate. Reducing prostate volume is thought to decrease the static component of BOO resulting from

BPE. The primary limitation of the androgen suppression hypothesis is that the pathophysiology of LUTS is not sufficiently dependent on prostate size.

Classification of Pharmacologic Agents

Surgical castration was reported to be an effective treatment for enlarged prostates in the 1890s (White, 1895; Cabot, 1896). Scott and Wade (1969) reported the first study investigating androgen suppression (medical castration) for LUTS and BPH. Cyproterone acetate, an antiandrogen, was reported to decrease symptoms and increase PFR in the majority of treated patients. The pharmacologic strategies of androgen suppression that have been investigated for LUTS and BPH over the past three decades are summarized in Table 104-7.

Caveats Related to Interpreting Androgen Manipulation Studies

The efficacy of androgen suppression in LUTS and BPH is presumed to be mediated by reduction of prostate volume. Maximal reduction of prostate volume after initiation of androgen suppression is achieved within 6 months (Peters and Walsh, 1987; Gormley et al, 1992). Therefore, randomized treatment must last at least 6 months to capture maximal therapeutic effect. Because the mechanism of action is by means of reduction of prostate volume, it is reasonable to assume that men with larger prostates achieve the greatest therapeutic benefit. The majority

of randomized, double-blind, placebo-controlled clinical trials evaluating androgen suppression enrolled men with larger prostates (Gormley et al, 1992 [finasteride]; Eri and Tveter, 1993a [Casodex] and 1993b [leuprolide]; McConnell et al, 1998 [finasteride]; and Roehrborn and colleagues, 2008a, 2010 [dutasteride]). The results of studies enrolling a disproportionate number of men with large prostates may not be generalizable to the “typical” patient with LUTS or BPH.

Review of the Literature

The overwhelming majority of drug studies evaluating androgen suppression were not randomized, enrolled small numbers of patients, and used qualitative outcome measures. This section reviews only multicenter, randomized, double-blind, placebo-controlled trials. Finasteride, a type 2 5 α -reductase inhibitor, and dutasteride, a dual inhibitor of both type 1 and type 2 5 α -reductase, represent the paradigm for androgen suppression and are emphasized in this section.

Finasteride

Finasteride is a competitive inhibitor of the enzyme 5 α -reductase (Vermeulen et al, 1989). Finasteride lowers serum and intraprostatic DHT levels. At least two isozymes (types 1 and 2) of 5 α -reductase exist (Jenkins et al, 1992). Finasteride is a selective inhibitor of the type 2 isozyme. Finasteride does not reduce DHT levels to castrate levels because circulating testosterone is converted to DHT by type I isozymes that exist in skin and liver (Thigpen et al, 1993). Gormley and coworkers (1992) reported the first multicenter, randomized, double-blind, placebo-controlled trial (often referred to as the North American Finasteride Trial) investigating the safety and efficacy of finasteride in 895 men with LUTS and BPH. The patients were randomized to receive placebo or 1 or 5 mg of finasteride for 1 year. The mean baseline prostate volumes in the placebo and 1- and 5-mg finasteride groups were 61, 61, and 59 cm³, respectively. The primary outcome measures were group mean changes in a modified Boyarsky symptom score (maximum score, 36) and PFR (Figs. 104-6 and 104-7). The group mean changes in symptom score, PFR, and prostate volume are shown in Table 104-8. The group mean percentage changes in symptom score at 12 months in the placebo and 1- and 5-mg finasteride groups were -2%, 9%, and 21%, respectively. The mean percentage changes in PFR were 8%, 23%, and 22% in the placebo and 1- and 5-mg finasteride groups, respectively. The mean percentage changes in prostate volume were -3%, -18%, and -19% in the placebo and 1- and 5-mg finasteride groups, respectively. The difference between the mean changes in PFR and prostate volume was statistically significant for both the 1- and the 5-mg finasteride groups versus the placebo group. The difference between the mean changes in symptom scores was statistically significant only for placebo versus 5 mg of finasteride. The dose-dependent symptom response was not associated with a dose-dependent prostate volume or PFR response. The changes in prostate volume were not directly related to the magnitude of the clinical response to finasteride. These observations suggest that the efficacy of finasteride may not be mediated exclusively by reduction of prostate volume. The incidences of decreased libido, ejaculatory disorder, and impotence were significantly greater in the finasteride groups compared with the placebo group. The treatment-related incidences of decreased libido, ejaculatory disorder, and impotence in the 1- and 5-mg treatment groups were 4.7%, 2.7%, and 3.7%, respectively, and 3.4%, 2.7%, and 1.7%, respectively. The percentage of patients withdrawing because of an adverse clinical event was equivalent in the three treatment groups. Prostate volume regression was maximal at 6 months. The greatest change in symptom scores and PFR occurred within the first 2 months of initiation of active treatment.

Andersen and associates (1995) reported the results of a multicenter, randomized, double-blind, placebo-controlled study investigating the safety and efficiency of finasteride in 707 Scandinavian patients maintained on randomized treatment for 2 years. The

Figure 104-6. Mean (\pm standard error) change in the total symptom score in men with benign prostatic hyperplasia during treatment with placebo (circles), 1 mg of finasteride (triangles), or 5 mg of finasteride (squares). The asterisks ($P \leq .05$), the pound symbols ($P < .01$), and the dagger ($P < .001$) indicate significant differences between the finasteride-treated groups and the placebo group. Month 0 represents the baseline. (From Gormley GJ, Stoner E, Bruskewitz RC, et al. The effect of finasteride in men with benign prostatic hyperplasia. *N Engl J Med* 1992;327:1185–91. Figure 104-7. Mean (\pm standard error) maximal urinary flow rates in men with benign prostatic hyperplasia during treatment with placebo (circles), 1 mg of finasteride (triangles), or 5 mg of finasteride (squares). The blue area indicates the range in which urinary flow was considered to be obstructed. Month 0 represents the baseline. Values before month 0 were obtained during the 2-week placebo run-in period. The asterisks ($P < .05$), pound symbols ($P < .001$), and daggers ($P < .01$) indicate significant differences between the finasteride-treated groups and the placebo group. (From Gormley GJ, Stoner E, Bruskewitz RC, et al. The effect of finasteride in men with benign prostatic hyperplasia. *N Engl J Med* 1992;327:1185–91. Copyright © 1992 Massachusetts Medical Society.)

mean baseline prostate volumes in the placebo and finasteride groups were 41.7 and 40.6 cm³, respectively. A modified Boyarsky symptom score was used to capture changes in symptom score. The differences in the group mean changes in the symptom score and PFR between finasteride and placebo after 12 and 24 months on active treatment are summarized in Table 104-8. The differences between the group mean changes in symptom scores and PFR after 1 year of randomized treatment are slightly less than in the North American Finasteride Study. This may be attributed to the smaller baseline prostate volumes.

Although the proportion of patients experiencing any adverse clinical event and the number of withdrawals caused by adverse clinical events were similar to those in the finasteride and placebo groups, there were more patients with sexual dysfunction in the finasteride versus placebo groups (19% vs. 10%). The placebo

response returns to baseline after 1 to 2 years, whereas the finasteride response remains stable. Andersen and colleagues (1995) interpret this to show that finasteride halts or alters the natural history of the disease.

Marberger and coworkers (1998) reported the results of a 2-year randomized, placebo-controlled trial of 3270 men receiving finasteride versus placebo that are comparable with those from the report of Andersen and associates (1995). The mean baseline prostate volumes in the placebo and finasteride groups were 39.2 and 38.7 cm³, respectively. The baseline prostate volume is the lowest of all the finasteride trials. The treatment-related improvements in the quasi-AUA symptom score at 1 and 2 years were 1.0 and 1.7 symptom units, respectively. The incidences of AUR were 1.0% and 2.5% in the finasteride and placebo groups, respectively.

Stoner (1994) and associates reported on the safety and efficacy of 3 years of therapy with finasteride. Patients participating in the North American and International Finasteride Studies were offered the opportunity to participate in an open-label extension study after completing 1 year of randomized therapy. The long-term (3-year) efficacy and safety analysis was limited to the 543 patients randomized to 5 mg. Of the 543 patients, 297 (55%) completed 3 years of treatment and were evaluable. Of the 246 unevaluable patients, 178 were dropouts and 68 were placed in a category indicating insufficient data. Inspection of the group mean changes in outcome measures reveals that the most precipitous changes in symptom scores, PFR, and prostate volume occurred between the 12- and the 18-month assessments, which coincides with transferring from blinded to unblinded treatment. After 18 months, the time-dependent changes were stable, suggesting durability of response. A subsequent report of the open-label extension study demonstrated the durability of finasteride effective up to 5 years (Hudson et al, 1999).

Boyle and coworkers (1996) reported a meta-analysis of six randomized, placebo-controlled clinical trials with finasteride. The mean group changes in symptom scores and PFR correlated with the mean baseline prostate volume. This observation accounts for the variability of treatment effect observed in the different studies.

The Proscar Long-Term Efficacy and Safety Study (PLESS) represented at the time the longest-duration multicenter, randomized, double-blind, placebo-controlled study reported in the medical therapy of BPH literature (McConnell et al, 1998). The 3040 men with moderate to severe urinary symptoms were randomized to receive daily finasteride, 5 mg, versus placebo for 4 years. A quasi-AUA symptom score was used. The baseline prostate volume in the study population was approximately 55 cm³, indicating a bias for enrolling men with markedly enlarged prostates. The mean

group changes in symptom score, PFR, and prostate volume throughout the study are shown for the finasteride and placebo in Figure 104-8. The treatment-related effects of finasteride on symptom score, PFR, and prostate volume were 2.0 symptom units, 1.7 mL/sec, and 32% size reduction for those patients on active treatment at the end of the study. The symptom and PFR improvement was modest and consistent with prior finasteride trials. PLESS demonstrated the durability of symptom and flow improvements with finasteride and very modest progression of these end points in the placebo group.

The unique findings of PLESS were related to incidences of both AUR and surgical intervention for LUTS and BPH (Fig. 104-9). The cumulative incidences of AUR at 4 years in the finasteride and placebo groups were 7% and 3%, respectively (57% risk reduction). The cumulative risk rates for undergoing BPH-related surgery were 10% and 5% in the placebo and finasteride groups, respectively (55% risk reduction). In men with prostate volumes greater than 55 cm³, the risk reduction of AUR and/or surgical intervention for finasteride was 70%. The risk reduction for AUR and BPH-related surgery was clinically relevant, especially in men with very large prostates. Men with significantly enlarged prostates and LUTS should therefore be advised of their significant risk of urinary retention and the beneficial effects of finasteride.

The PLESS study also provided insights into the impact of finasteride on the detection of prostate cancer. The decision to pursue the diagnosis of prostate cancer in the study was left at the discretion of the principal investigator and therefore represents standard practice. The detection of prostate cancer was not significantly different in the placebo and finasteride group, suggesting that finasteride does not mask the diagnosis of prostate cancer (Andriole et al, 1998).

Tammela and Kontturi (1993) reported a randomized, double-blind, placebo-controlled study examining the effects of finasteride on BOO in 36 men on a routine waiting list for prostatectomy. The mean prostate volumes in the finasteride and placebo study groups were 50 and 48 cm³, respectively. The mean baseline detrusor pressures at maximum flow in the placebo and finasteride groups were 115 and 126 cm H₂O, respectively, indicating that the patients were severely obstructed. The group mean changes in detrusor pressure at maximum flow were +3 and −39 cm H₂O in the placebo and finasteride groups, respectively. Although the difference between placebo and finasteride was highly statistically significant, the overwhelming majority of the finasteride-treated patients remained obstructed after treatment. The marked treatment-related changes in detrusor pressure were not associated with statistically significant changes in symptom scores. The authors did not comment on whether the changes in detrusor pressures correlated

Figure 104-8. The effect of finasteride or placebo on symptom scores (on the quasi-American Urological Association Symptom Index), prostate volume, and maximal urinary flow rate over time. Values are mean (\pm standard error) changes from baseline. The numbers below the panels show the numbers of patients with valid data who remained in the study. (From McConnell JD, Bruskewitz R, Walsh P, et al. The effect of finasteride on the risk of acute urinary retention and the need for surgical treatment among men with benign prostatic hyperplasia. *N Engl J Med* 1998;338:557-63.)

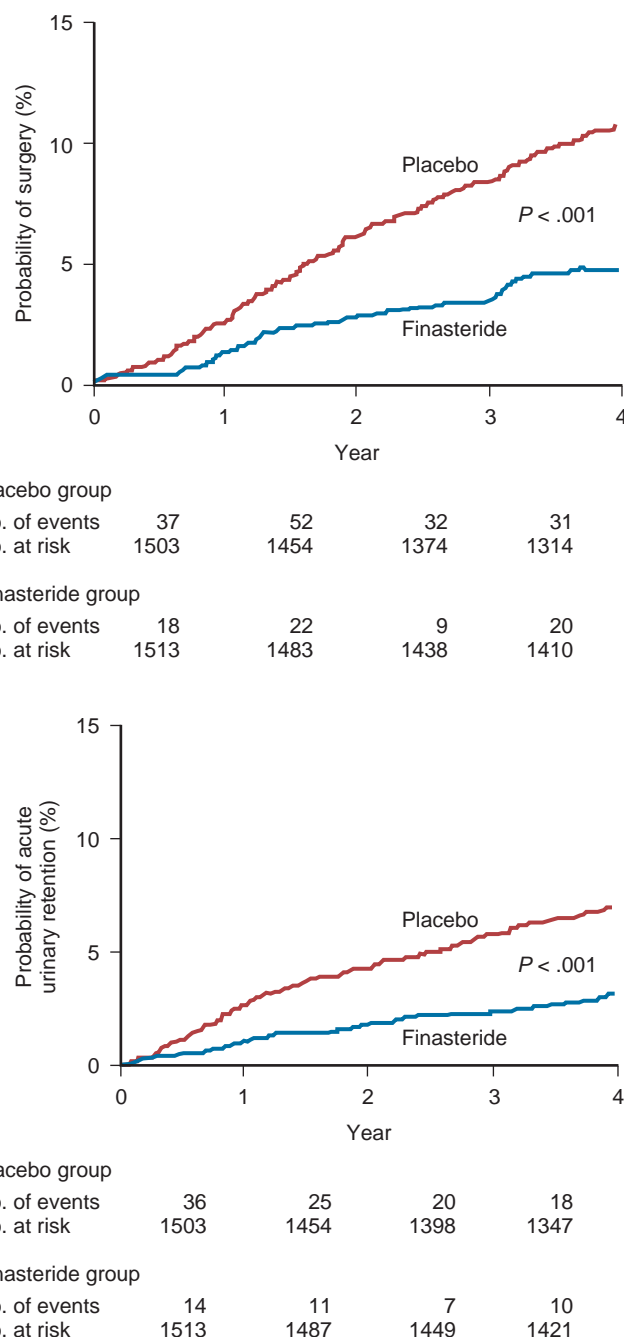

Figure 104-9. Probability of undergoing surgery for benign prostatic hyperplasia or the development of acute urinary retention during the 4-year study period in the placebo and finasteride groups. The figure shows life-table analyses of the proportion of men with each outcome. The numbers of events shown below the graphs are those that occurred during each 1-year interval. The numbers of men at risk are those at the beginning of the respective 1-year intervals. Data on men who died, were given a diagnosis of prostate cancer, or were lost to follow-up were censored at the time of death, diagnosis of prostate cancer, or discontinuation of therapy. (From McConnell JD, Bruskewitz R, Walsh P, et al. The effect of finasteride on the risk of acute urinary retention and the need for surgical treatment among men with benign prostatic hyperplasia. *N Engl J Med* 1998;338:557-63. Copyright © 1998 Massachusetts Medical Society.)

with changes in prostate volume. Of the patients participating in the randomized, double-blind study, 27 completed a 4-year open-label extension study (Tammela and Kontturi, 1995). The detrusor pressure at maximum flow showed further improvements over time.

PSA has become widely accepted as a screening instrument for prostate cancer (Tchetgen and Oesterling, 1995). An elevated or significantly rising PSA value is often an indication for prostatic biopsy. Finasteride reduces group mean serum PSA levels approximately 50% (Guess et al, 1993). The effect of finasteride on individual serum PSA levels is highly variable. **Because of the variable effect on PSA, men who are candidates for early detection of prostate cancer should have their PSA level determined before beginning finasteride therapy.** A biopsy should be considered if the PSA level is elevated or for progressively rising PSA levels after initiation of therapy.

The Prostate Cancer Prevention Trial (PCPT) (Thompson et al, 2003) showed that finasteride reduced the incidence of diagnosed prostate cancer (vs. placebo). There was an increased incidence of high-grade disease, possibly because of the volume change effect, which was also seen with dutasteride in the later REDUCE trial (Andriole et al, 2011). See Chapter 107 for further details of PCPT and REDUCE.

Gross hematuria is a relatively rare, yet troublesome, manifestation of LUTS and BPH. Puchner and Miller (1995) reported an uncontrolled personal experience of 18 LUTS and BPH patients treated with finasteride for refractory gross hematuria secondary to BPH. Of the 18 reported cases, 12 patients had undergone a prior prostatectomy. Finasteride was very effective in relieving the postprostatectomy gross hematuria. Miller and Puchner (1998) reported a follow-up series that demonstrated the long-term effectiveness of finasteride for the treatment of hematuria from BPH. Carlin and coworkers (1997) reported resolution of gross hematuria in 12 of 12 men treated with finasteride. **These preliminary observations have been confirmed by a randomized, double-blind, placebo-controlled study by Foley and associates (2000) demonstrating that finasteride prevents recurrent gross hematuria secondary to BPH.** Gross refractory hematuria recurred within 1 year for 63% and 14% of men randomized to placebo and finasteride, respectively.

Dutasteride

Dutasteride is a dual inhibitor of 5 α -reductase 1 and 2 and therefore has a greater impact on suppressing serum DHT levels (Clark et al, 2004). In an RCT of 4325 men (2951 completed) Roehrborn and colleagues (2002) reported that serum DHT was reduced by 90.2%. The symptom score was improved by 4.5 points (21.4%) ($P < .001$), and the maximal flow rate improved significantly by 2.2 mL/sec ($P < .001$) at 24 months. The risk reduction for AUR was 57%, and the risk reduction for BPH-related surgery was 48% compared with placebo. Debruyne and colleagues (2004) reported the pooled results of a 2-year open-label extension study in which both dutasteride- and placebo-treated groups received dutasteride 0.5 mg/day. Significant improvements in symptom scores and maximal flow rates were observed in both study groups. It was concluded that long-term treatment with dutasteride results in continuing improvements in both symptoms and urinary flow and that the risk reduction for AUR and BPH-related surgery was durable over 4 years. **Similar to finasteride, the principal side effects were loss of libido and ED, but these were most frequently seen at the start of therapy and declined over time with treatment.** Roehrborn and coworkers (2004) reported similar results and confirmed 93% suppression of DHT at 4 years. The results of the REDUCE study of dutasteride versus placebo in terms of their ability to prevent prostate cancer have been reported by Andriole and colleagues (2009). **A 23% reduction in prostate cancer overall was seen in the dutasteride arm, but with a small increase in Gleason 8+ cancers in the treatment arm.** In December 2010 the FDA Oncologic Drugs Advisory Committee voted against use of dutasteride for reduction in the risk of prostate cancer, and the manufacturer has withdrawn this application. **Beneficial effects on symptoms, Qmax, and risk**

of progression were also seen in this group of men at high risk for LUTS and BPH progression as well as for a prostate cancer diagnosis. More recent publications have explored the relative benefits of tamsulosin and dutasteride in the 4-year Combination of Avodart and Tamsulosin (CombAT) study (Montorsi et al, 2011; Roehrborn et al, 2011, 2012) and show a benefit for combination therapy and correlation between patient satisfaction and the improvement in IPSS. The only genuine head-to-head comparison of finasteride and dutasteride, published by Nickel and colleagues in 2011, reported similar reductions in prostate volume and improvements in Qmax and LUTS and similar adverse events in 1600 men with enlarged prostates.

Zanoterone

Zanoterone is a steroidal competitive adrenoceptor antagonist (Juniewicz et al, 1993). Berger and coworkers (1995) reported a multicenter, randomized, double-blind, placebo-controlled study in 463 patients receiving placebo and 100, 200, 400, or 800 mg of zanoterone for 6 months. The group mean changes in AUA symptom score were not reported; however, the differences between placebo and all of the zanoterone groups were not statistically significant. It is interesting to note that the differences between the percent group mean changes in serum PSA in all of the active treatment groups were significantly greater than those in the placebo group, despite the lack of an apparent drug effect on prostate volume. Fifty-six percent and 22% of all zanoterone patients reported breast pain and gynecomastia, respectively. The incidence and severity of adverse clinical events and the equivocal efficacy precluded further development of this drug for LUTS and BPH.

Flutamide

Flutamide is an orally administered nonsteroidal antiandrogen that inhibits the binding of androgen to its receptor (Sufrin and Coffey, 1973). The first reported randomized, double-blind, placebo-controlled trial in LUTS and BPH examined the safety and efficacy of flutamide in 31 men with symptomatic BPH (Caine et al, 1975). Statistically significant differences were not observed between placebo and 300 mg of flutamide for symptoms, prostate size, PVR, and PFR. Stone (1989) reported a multicenter, randomized, double-blind study comparing flutamide and placebo in men with LUTS and BPH. Eighty-four patients were randomized to receive 24 weeks of either flutamide, 250 mg three times a day, or placebo. Of the 84 patients, 58 (69%) and 12 (14%) were evaluable at 12 and 24 weeks on double-blind treatment. The small sample size at 24 weeks precludes any meaningful conclusions. The between-group comparisons of group mean changes from baseline for placebo versus flutamide were not statistically significant at any time point. The incidences of breast tenderness and diarrhea in the flutamide group were 53% and 11%, respectively. Although the interim analysis was reported in 1989, a subsequent report of the multicenter study has not been published.

Cetorelix

Cetorelix is a gonadotropin-releasing hormone antagonist that has been investigated for LUTS and BPH. A potential advantage of a gonadotropin-releasing hormone antagonist over the luteinizing hormone-releasing hormone agonists in the treatment of LUTS/BPH is the ability to titrate the level of androgen suppression. This would be clinically relevant if different levels of androgen suppression mediate prostate size reduction and adverse events (hot flashes, decreased libido, ED). An open-label study of 11 men demonstrated that cetorelix reduced prostate volume and improved LUTS without significant adverse events. Lepor and coworkers (1997) reported a proof-of-concept randomized, double-blind, placebo-controlled study of cetorelix in men with LUTS or BPH. After an 8-day placebo lead-in, men received daily subcutaneous injections of placebo or 1 mg of cetorelix (group C₀₁) for 27 days. One group received loading doses of 10 mg of cetorelix on the first 4 days of active

treatment (C_{10}). Maximal lowering of testosterone was observed within 24 hours. The testosterone level was reduced to castrate levels in the C_{10} group and to intermediate testosterone suppression level in the non-loading-dose group (C_{01}) (approximately 0.20 ng/dL). Men exhibiting a clinical effect were followed for 1 year. In the C_{10} and C_{01} groups, treatment-related improvements in AUA symptom score were 3.0 and 2.0 symptom units, respectively. In both the C_{10} and the C_{01} groups, the treatment-related improvement in PFR was 2.0 mL/sec. The treatment-related reductions of prostate volume were 5.5 and 3.0 cm³, respectively. The treatment-related incidence of hot flushes and sexual dysfunction in the C_{01} group was negligible. During the open-label extension, prostate volume did not return to baseline, suggesting a prolonged effect on the disease. Because of problems with the drug formulation, phase 3 studies with cetrorelix were not pursued until recently (Debruyne et al, 2008).

In this dose-finding study, three dosing regimens were explored: one or two injections weekly for 4 weeks. In all groups a rapid improvement in mean IPSS was obtained, with a peak effect of −5.4 to −5.9 (placebo, −2.8). Changes from baseline and differences from placebo were statistically significant up to week 20. Placebo response was less sustained than usually seen with oral preparations. A subsequent study showed that intramuscular injections achieved rapid symptom and flow improvements that were maintained for 6 months (Debruyne et al, 2010).

The primary disadvantage of cetrorelix and other gonadotropin-releasing hormone antagonists will be the requirement for an injection and the cost. If single-injection therapy provides desirable clinical response (e.g., over 6 months) with minimal adverse events, there may exist a role for these antagonists in the treatment of LUTS and BPH.

Chlormadinone Acetate

Fujimoto and colleagues explored the use of a potent progesterone-derived antiandrogen, chlormadinone acetate (CMA), in 114 men in a multicenter, single-cohort prospective study. This agent is used clinically as a hormonal contraceptive. They found a decrease of 25% in prostate volume at week 16, with improvements in symptom scores and flow but deterioration in sexual function (Fujimoto et al, 2013), so it may have a role in sexually inactive older men.

Aromatase Inhibitors

The rationale for aromatase inhibition is that estrogens may be involved in the pathogenesis of BPH. The estrogenic effect most likely mediates stromal-epithelial interactions that regulate the proliferative activity of the prostate. Several observations support the role of stroma in the development of BPH and the influence of estrogens on prostatic stroma. The inductive potential of prostatic mesenchyme (stroma) is supported by the observation of Cunha and colleagues (1980) in a mouse embryonic animal model. Coffey and Walsh (1990) reported that estrogen treatment of castrated beagles produced a threefold to fourfold increase in the total amount of prostatic stroma. Estrogens also greatly enhanced the ability of androgens to induce BPH in a canine model (Walsh and Wilson, 1976; DeKlerk et al, 1979). This synergistic effect may be mediated by the ability of estrogens to upregulate prostatic adrenoceptor content. Stromal hyperplasia can be induced in the prostates of dogs and monkeys treated with aromatizable androgens and prevented by aromatase inhibitors such as atamestane (Habenicht et al, 1987; Habenicht and el Etreby, 1989).

Atamestane is a highly selective aromatase inhibitor that lowers both serum and intraprostatic levels of estradiol and estrone (el Etreby et al, 1991). Gingell and coworkers (1995) reported a multicenter, randomized, double-blind, placebo-controlled study comparing placebo and 400 mg of atamestane in 160 patients with LUTS and BPH. Atamestane resulted in a statistically significant decrease in serum estradiol and estrone levels and a statistically significant increase in serum testosterone. No statistically significant group mean differences were observed for changes in Boyarsky symptom score, PFR, or prostate volume between the

atamestane and the placebo groups. One of the explanations contributing to the failure of atamestane to achieve clinical efficacy was the increase in testosterone. The development of atamestane for LUTS and BPH was suspended because of these negative clinical findings. The failure to demonstrate that atamestane causes regression of established BPH or clinical improvement does not negate the influence of estrogens in the pathogenesis of BPH.

Finasteride and dutasteride are the only drugs available so far that achieve androgen suppression with acceptable tolerability. Both symptoms and flow rates are improved, especially in men with larger glands. Impotence and decreased ejaculatory volume are the primary treatment-related adverse experiences. The literature also suggests that finasteride and dutasteride may be offered to men with hematuria secondary to friable prostatic tissue and to men with LUTS and enlarged prostates who elect to reduce their risk of developing urinary retention.

Summary

Multicenter, randomized, double-blind, placebo-controlled studies of finasteride and dutasteride support their role in the treatment of LUTS and BPH. Finasteride reduces prostate volume approximately 20%. The overall treatment-related improvements in symptom score (approximately 1.0 symptom unit) and PFR (approximately 1.5 mL/sec) relative to placebo are modest. Long-term safety and durability of efficacy have been demonstrated for finasteride. The adverse clinical events associated with finasteride are minimal and are related primarily to sexual function. Finasteride is effective in the management of gross hematuria associated with BPH, especially in the presence of friable prostate tissue. Dutasteride is an inhibitor of both type 1 and type 2 5 α -reductase and has efficacy and side effects similar to those of finasteride. Finasteride and dutasteride alter the natural history of urinary retention in men with LUTS and enlarged prostates. In selected patients with larger prostates, over longer time periods, dutasteride appears to have symptomatic benefits greater than tamsulosin. In the REDUCE study, dutasteride reduced the incidence of prostate cancer by 23% with a small increase in high-grade tumor incidence, about which patients should be informed. Antiandrogens have also been investigated for LUTS and BPH. These studies failed to demonstrate statistically significant treatment-related efficacy. The equivocal efficacy and problematic toxicity of antiandrogens limited the enthusiasm for marketing these drugs for the treatment of LUTS and BPH. The role of gonadotropin-releasing hormone antagonists requires further study.

COMBINATION THERAPY WITH α -BLOCKER AND 5 α -REDUCTASE INHIBITOR

Lepor and coworkers (1996) reported the first multicenter, randomized, double-blind trial comparing placebo, finasteride, terazosin, and combination therapy (finasteride and terazosin) in 1229 U.S. veterans with clinical BPH. Of the 1229 patients randomized, 1007 (81.9%) completed the 1-year randomized treatment on assigned study medication.

The mean group differences between finasteride and placebo were not statistically significant for AUA Symptom Index, Symptom Problem Index, BPH Impact Index, and PFR. The mean group differences between terazosin versus placebo and terazosin versus finasteride for all of the outcome measures other than prostate volume were highly statistically significant. The group mean differences between combination therapy and terazosin for all of the outcome measures other than prostate volume were not statistically significant owing to the lack of treatment-related efficacy of finasteride over this period. The VA study demonstrated the superiority of α -adrenergic blockade over androgen suppression for the treatment of LUTS and BPH over a 1-year interval. Prostate volume decreased approximately 20% in the finasteride and combination groups. The numbers of patients withdrawing from the study

* $P < .05$ relative to placebo.

PREDICT, Prospective European Doxazosin and Combination Therapy Trial.

because of adverse clinical events in the finasteride, terazosin, and combination groups were similar.

A multicenter, randomized, double-blind, placebo-controlled study comparing placebo, doxazosin, finasteride, and combination therapy confirmed the findings of the VA Cooperative Study (Kirby et al, 2003). In the Prospective European Doxazosin and Combination Therapy Trial (PREDICT), 1089 men were randomized in equal proportions to one of the just discussed four treatment groups for 1 year. The daily dose of doxazosin was titrated up to 8 mg. The baseline prostate volume was approximately 36 cm³. The group mean improvement of AUA symptom score and PFR and change in prostate volume between baseline and final study visit are shown in Table 104-9.

A multicenter, double-blind study compared SR alfuzosin (5 mg), finasteride (5 mg), and combination therapy in 1051 men receiving active treatment for 6 months (Debruyne et al, 1998). The improvement in IPSS was not significantly different in the alfuzosin versus combination groups. At 6 months, there were no significant differences between PFR among any of the treatment groups.

Medical Therapy of Prostatic Symptoms (MTOPS) Trial

The results of all three large-scale studies just described appear to suggest that the role of 5 α -reductase inhibitors as generalized monotherapy for LUTS may be somewhat limited, a finding at variance with some of the original studies on finasteride. An additional, longer-term trial, which had been progressing in parallel to these studies, generated important new information on both the clinical potential of 5 α -reductase inhibitors as monotherapy and the potential of drug combinations. The Medical Therapy of Prostatic Symptoms (MTOPS) trial, a prospective, randomized, double-blind, multicenter, placebo-controlled trial, was established to determine whether medical therapy can prevent or delay the progression of LUTS or BPH in the long term. Further elucidation of the natural history of BPH, determining baseline factors associated with more rapid disease progression, was a secondary aim of the study.

In 18 academic centers across the United States a total of 3047 patients were recruited and randomized to receive doxazosin, finasteride, a combination of both, or placebo. Mean age of participants was 62.6 years; most were white (82.6%), with 8.8% black and 7.2% Hispanic participants. The inclusion and exclusion criteria allowed men with all prostate sizes to be enrolled, as long as the serum PSA was less than 10 ng/mL. This resulted in a wide distribution of prostate sizes and serum PSA values, allowing for stratified analyses of subsets based on these criteria (McConnell et al, 2003).

Disease progression was defined as a worsening of LUTS according to the AUA symptom score (AUA symptom score is identical to IPSS scoring system). Progression was deemed to have occurred in the case of one of the following: a 4-point rise in AUA symptom score confirmed by a second visit within 4 weeks; a 50% increase in creatinine relative to baseline levels; AUR; two or more UTIs within 1 year or a single episode of urosepsis caused by BOO; and socially unacceptable incontinence. The first occurrence of any of these events indicated LUTS or BPH progression. Progression as an end point represented a novel concept at the time of the initiation of the MTOPS study, although PLESS as well as the dutasteride studies later used AUR and surgery as end points in the study design

(McConnell et al, 1998; Roehrborn et al, 2002). Entirely novel was the concept of using a threshold to define symptom progression. Based on data from the VA Cooperative Study, in which men perceived general improvement in their symptom status once the AUA symptom score improved by more than 3 points, a threshold of 4 points was chosen—to be confirmed within 4 weeks—to indicate global subjective worsening of symptom status.

To assess the natural history of LUTS and BPH, Qmax, prostate volume, sexual function, and quality of life were regularly recorded with respect to BPH symptoms. Transrectal ultrasound and DRE were used to evaluate prostate volume, the Sexual Function Inventory questionnaire evaluated sexuality, and the Short Form-36 Health Survey instrument recorded quality of life scores. Prostatic biopsies were obtained at baseline and at 5 years (or at primary end point) in 37% of study participants who volunteered to take part in a biopsy substudy. Patients were randomized to receive 5 mg finasteride and doxazosin placebo, 5 mg finasteride and doxazosin titrated up to 8 mg, titrated doxazosin and finasteride placebo, or two placebo drugs.

The results of the MTOPS trial suggest that the combination of doxazosin and finasteride exerts a clinically relevant, positive effect on rates of disease progression. Men who received combination therapy were significantly less likely to experience LUTS and BPH progression than those receiving either monotherapy or placebo, with risk reduction rates of 39% for doxazosin, 34% for finasteride, and 67% for combination therapy compared with placebo.

Invasive therapy and AUR risk were significantly reduced by finasteride and combination therapy (by 69% and 64% and by 79% and 67%, respectively), whereas all treatment regimens (placebo, doxazosin, finasteride, and combination) brought about a significant improvement in AUA symptom score (4.0, 6.0, 5.0, and 7.0, respectively) and Qmax (1.4, 2.5, 2.2, and 3.7 mL/sec, respectively) at 4 years (Figs. 104-10 and 104-11). AUA symptom score and Qmax improved significantly more in the combination therapy group compared with the monotherapy groups, whereas adverse events were similar to previously reported studies.

In addition to indicating the potential benefits of combination therapy, MTOPS provided important data regarding the natural history of untreated LUTS and the prediction of LUTS patients who will respond most effectively to medical treatment. Although the patients receiving finasteride alone or in combination experienced the expected decrease in prostate volume, patients on placebo or doxazosin alone experienced an increase in prostate volume from a baseline of 34.0 mL by 9.3 (30.3%) (placebo) and from 36.4 mL by 9.9 (31.4%) (doxazosin), respectively. Stratified by PSA quartiles, total prostate volume in both placebo and doxazosin-treated patients increased from 4.9 mL (24.9%) to 16.2 mL (34.5%) from the lowest to the highest quartile for an annualized growth of 1.1 to 3.6 mL/yr. These findings suggest that doxazosin, despite its apoptotic effect (Glassman et al, 2001), does not interfere with the natural growth tendency of the prostate gland and that baseline PSA is a useful predictor of future prostate growth in men with LUTS and BPH.

Examination of baseline measures and the disease outcomes of 737 patients treated with placebo revealed that PSA, Qmax, PVR, and prostate volume at baseline correlated with clinical progression of the disease and the need for BPH-related surgery ($P = .03$ to

Figure 104-10. Cumulative incidence of progression in the Medical Therapy of Prostatic Symptoms (MTOPS) trial. (From McConnell JD, Roehrborn CG, Bautista OM, et al. The long-term effect of doxazosin, finasteride, and combination therapy on the clinical progression of benign prostatic hyperplasia. *N Engl J Med* 2003;349[25]:2387–98.)

< .001). Age was linked to clinical progression ($P < .001$), and AUA symptom score correlated with need for surgery ($P = .002$). Baseline PSA and prostate volume correlated with risk of AUR ($P = .03$ to $.003$). Risk of progression, BPH-related surgery, and AUR increased alongside levels of serum PSA. In medically treated patients, however, baseline values were variably predictive of LUTS or BPH outcome. In doxazosin-treated patients, for example, PSA, Qmax, and prostate volume were predictive of outcome; however, this was not true of patients treated with finasteride alone or combined therapy.

The number needed to treat (NNT) to prevent a case of LUTS or BPH progression as defined in MTOPS in the overall population was 8.4 for the combination therapy group and 13.7 and 15.0, respectively, for the doxazosin- and finasteride-treated patients. For those men treated with combination therapy who had a baseline PSA of more than 4.0 ng/mL, however, the NNT was 4.7, and for those with a prostate volume over 40 mL it was 4.9, suggesting that combination therapy becomes an economically stronger option in patients at higher risk for progression.

The link between sexual dysfunction and severity of LUTS was also confirmed by the MTOPS data. A correlation was observed between LUTS and five domains of sexual dysfunction (libido, sexual function, ejaculatory function, the patient's assessment of his sexual problems, and overall satisfaction). In addition, men with larger prostates were more likely to have low libido, low overall sexual functioning, reduced ejaculatory function, and greater sexual problems.

Another study of combination therapy in LUTS and BPH using dutasteride and tamsulosin has been reported by Barkin and colleagues (2003). Three hundred twenty-seven patients were treated with both drugs for 24 weeks, and then the α -adrenergic blocker was withdrawn for a further 12 weeks; of those patients with an IPSS less than 20, 84% continued without noticeable deterioration of their symptoms. In contrast, in the 27% of patients with more severe symptoms (IPSS higher than 20), 42.7% reported a worsening of their symptoms compared with 14% of those who remained on combination therapy. It was concluded that a 5 α -reductase inhibitor can be used in combination with an α -adrenergic blocker to achieve rapid onset of symptom relief in

patients at risk of underlying disease progression and the α -adrenergic blocker can then be discontinued. In patients with severe symptoms, combination therapy should be continued for a longer term.

Combination of Avodart and Tamsulosin (CombAT) Study

Roehrborn and colleagues (2008a, 2010) have reported the 2-year and 4-year results of the CombAT study. In men with a pretreatment PSA between 1.5 and 10 ng/mL, the combination of dutasteride and tamsulosin was more effective than either drug alone. It is interesting to note that in men with larger prostates, although the tamsulosin effect was rapid, over time dutasteride was the more effective agent. The 4-year data showed that combination therapy was significantly superior to tamsulosin monotherapy but not dutasteride monotherapy at reducing the relative risk of AUR or BPH-related surgery. Further analysis also showed that men with a prostate volume of 40 mL or more and baseline PSA levels of 1.5 ng/mL or higher had greater reductions in the risk ratio (RR) of AUR or BPH-related surgery and greater reductions in the RR of clinical progression and symptom deterioration on combined therapy or dutasteride monotherapy than on tamsulosin monotherapy (Roehrborn et al, 2011). In addition, combined therapy with dutasteride plus tamsulosin provided better long-term control (up to 4 years) of both storage and voiding LUTS compared with monotherapy for men with prostate volumes of 30 mL or greater (Montorsi et al, 2011; Roehrborn, 2012).

The inclusion criteria for the MTOPS and CombAT studies were different for prostate volume and PSA at entry. Whereas the baseline characteristics for age, total IPSS, Qmax, and PVR were remarkably similar (Table 104-10), the patient groups were significantly different with regard to mean prostate volume (36.3 mL vs. 55.0 mL) and mean PSA (2.4 ng/mL vs. 4.0 ng/mL) for MTOPS and CombAT, respectively. This resulted in significantly different outcomes and responses to medication. In the patients with larger prostates in the CombAT study, the 5 α -reductase inhibitor dutasteride achieved greater improvements (reductions in IPSS) compared with the α -blocker tamsulosin in both symptom score (-5.3 vs. -3.8) and flow rate ($+2.0$ mL/sec vs. $+0.7$ mL/sec), something not seen in

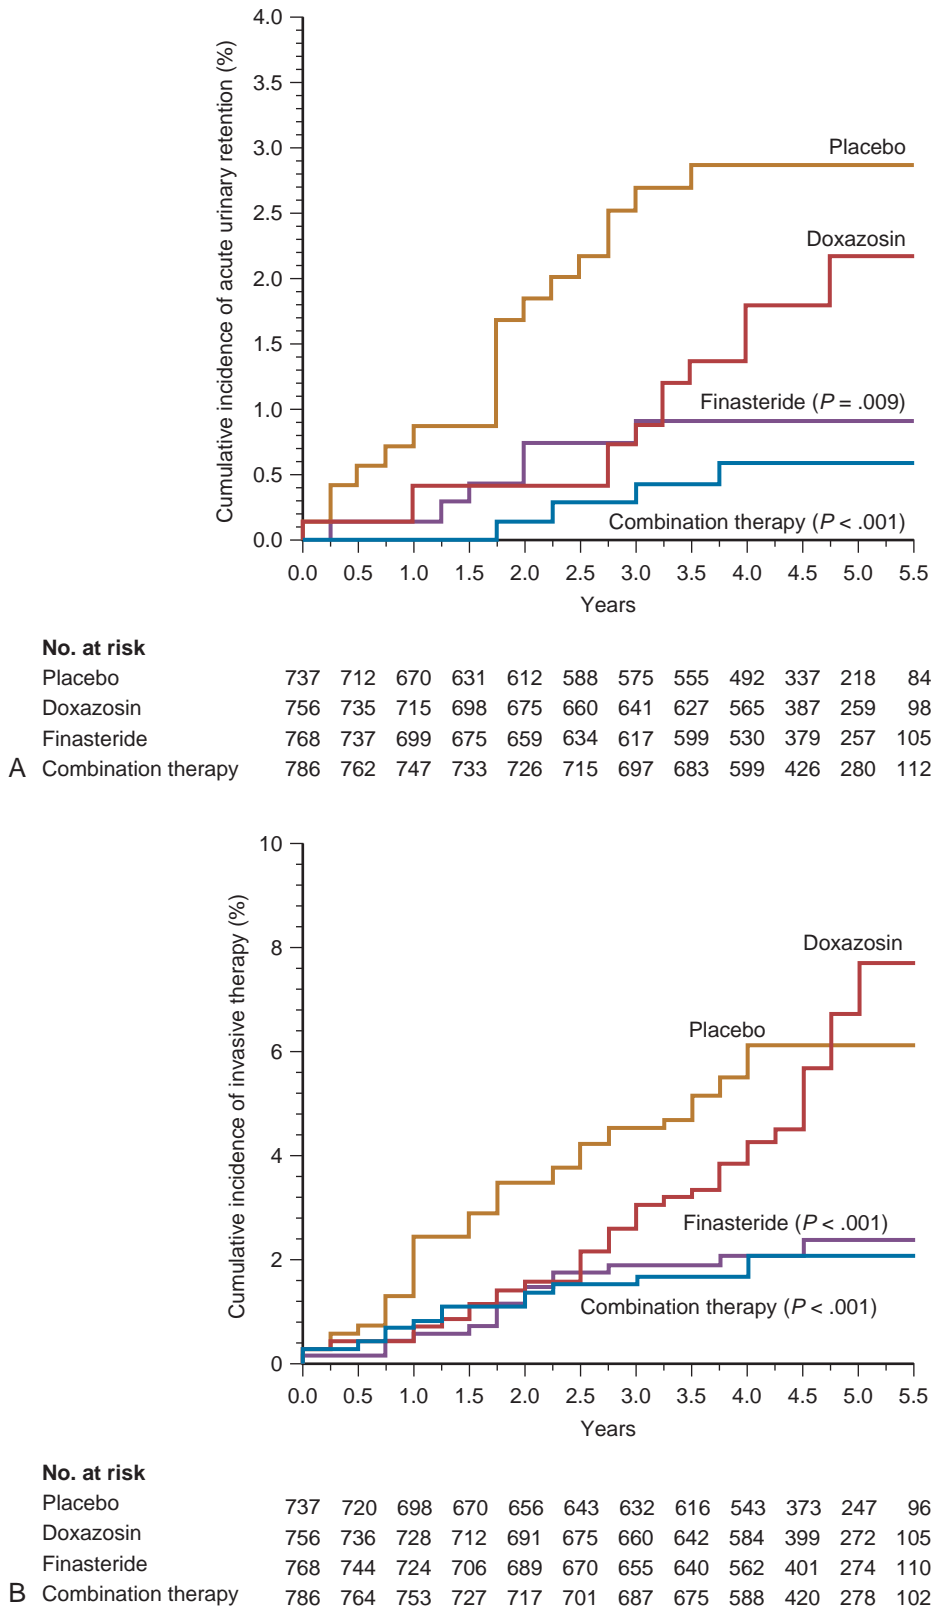

Figure 104-11. Cumulative incidence of acute urinary retention (A) and invasive therapy for benign prostatic hyperplasia (B) in the Medical Therapy of Prostatic Symptoms (MTOPS) trial. (From McConnell JD, Roehrborn CG, Bautista OM, et al. The long-term effect of doxazosin, finasteride, and combination therapy on the clinical progression of benign prostatic hyperplasia. *N Engl J Med* 2003;349[25]:2387-98.)

other comparative studies. The comparable improvements with combination therapy (dutasteride and tamsulosin) were −6.3 and +2.4 mL/sec.

ANTICHOLINERGIC (ANTIMUSCARINIC) RECEPTOR BLOCKERS

There is an overlap between symptoms traditionally regarded as being caused by LUTS and BPH and those ascribed to the syndrome of OAB. OAB symptoms may coexist with LUTS and BPH or BOO and may be either secondary to that obstruction or unrelated. Telephone surveys in the United States (Stewart et al, 2003) and in Europe (Milsom et al, 2001) show about 12% to 16% of the adult population admit to OAB symptoms. In Europe, 60% of those with symptoms had consulted a medical practitioner about the symptoms, and two thirds reported that they had an effect on daily living. Traditionally, in the treatment of OAB symptoms the use of antimuscarinic (commonly called *anticholinergic*) agents is often used in women. However, in men there was always anxiety that these antimuscarinic agents decrease detrusor contractility and could, in theory, increase the risk of urinary retention, particularly in a man with significant obstruction. If AUR did not result, then the risk of increasing PVR might lead to other complications such as infection.

There have been small studies and anecdotal evidence showing that antimuscarinic agents can be used judiciously with efficacy and with minimal side effects. More recently, newer antimuscarinic agents have been introduced. Tolterodine studies have shown symptomatic benefit without increased AUR in men with OAB with proven BOO (Abrams et al, 2006), suggesting that antimuscarinics can be safely administered in men with BOO. Abrams and colleagues (2006) investigated a total of 222 men older than 40 years with BOO and detrusor overactivity confirmed by pressure-flow studies who were enrolled and were randomized to tolterodine (2 mg twice daily in 149) or placebo (in 72) for 12 weeks; 87% completed the trial. Primary end points were Qmax and detrusor pressure at maximal flow rate (pdetQmax). Median treatment differences in Qmax (−0.7 mL/sec, 95% confidence interval [CI] −1.6 to 0.4) and pdetQmax (−7 cm H₂O, 95% CI −3 to 11) were comparable. Tolterodine significantly reduced the Bladder Outlet Obstruction Index score versus placebo (−9 vs. 0, $P < .02$), although the urodynamic significance of these changes has been questioned. There were significant treatment differences in volume to first detrusor contraction (+59 mL, 95% CI 19–100) and maximum cystometric capacity (+67 mL, 95% CI 35–103), favoring tolterodine over placebo ($P < .003$). Change in PVR was significantly greater among patients treated with tolterodine (+25 mL) than placebo (0 mL, $P < .004$), but there were no significant between-group differences in the incidence of adverse events. Urinary retention was reported by one patient treated with placebo. Tolterodine did not appear to

adversely affect urinary function in men with OAB and BOO. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. Tolterodine was also well tolerated. These results suggest that antimuscarinics could be safely administered in men with BOO.

Martin-Merino and colleagues (2009) showed in a population-based, retrospective cohort study using a large primary care database of patients who received antimuscarinic agents for more reasons than just urologic symptoms that the overall incidence of AUR in the study cohort (1844) was 1.0 per 1000 person-years, with the incidence rate increasing with age. Roehrborn and coworkers concluded that men prescribed antimuscarinic agents, particularly for urogenital conditions, should be closely monitored during the first 30 days of treatment for signs or symptoms of urinary retention, when the risk was fourfold higher than later (Martin-Merino et al, 2009).

Blake-James and colleagues (2007) performed a systematic review of the available literature and, when there were sufficient data, performed a meta-analysis to assess the safety and efficacy of antimuscarinic therapy in men with LUTS or BPH. They analyzed five RCTs and 15 observational studies of good quality (Table 104-11). Minimal changes were reported in Qmax or IPSS overall, although storage symptoms scores did appear to improve in one RCT. PVR did increase, but minimally, and there was no convincing increase in AUR rates. The authors concluded that although the therapy was safe, more studies were required to define the efficacy of antimuscarinic therapy for men with LUTS or BPH.

Combination Therapy: α -Adrenergic Blockers and Anticholinergic (Antimuscarinic) Receptor Blockers

Response of the OAB symptoms seen in men with LUTS or BPH raises the possibility that a combination with α -blocker therapy could reduce the risk of retention or deteriorating bladder function, but also could add to the treatment of the remaining obstructive symptoms of LUTS or BPH (Athanasopoulos et al, 2003).

In a Korean randomized study (Lee et al, 2005), 211 men with OAB symptoms and urodynamically proven BOO were randomized (1:2) into two groups, one given doxazosin (4 mg once daily) only and the other given propiverine (20 mg once daily) plus doxazosin for an 8-week trial. Significant improvements were noted in each group after treatment in urinary frequency, maximum flow rate, average micturition volume, and IPSS. Improvement in urinary frequency (23.5% vs. 14.3%, $P = .004$), average micturition volume (32.3% vs. 19.2%, $P = .004$), and storage (41.3% vs. 32.6%, $P = .029$) and urgency ($P = .019$) symptoms were more significant in group 2, given propiverine plus doxazosin. PVR urine was found to be significantly increased only in group 2, but this was not accompanied by urinary retention. Patient satisfaction rates were found to be significantly higher in group 2 than in group 1 ($P = .002$). Overall adverse event rates were higher in group 2 ($P = .002$), although discontinuation rates and discontinuation rates resulting from adverse events were not different between the two groups, suggesting that combination therapy consisting of α_1 -adrenoceptor antagonists with antimuscarinics represents an effective and relatively safe treatment modality in select patients with OAB coexisting with benign prostatic obstruction.

Kaplan and coworkers (2006), in a double-blind placebo-controlled trial in 95 centers in the United States, enrolled 879 men with the usual LUTS and BPH parameters often found in trials, but who also had proven frequency (minimum eight times a day) and urgency (at least three episodes per 24 hours as recorded in voiding diaries) and randomized them among tolterodine 4 mg daily, tamsulosin 0.4 mg daily, a combination of tolterodine and tamsulosin, and placebo over a 12-week period. The combination group showed a significant benefit over placebo in response to a patient-reported single-item question determining the perception of benefit (80% vs. 62%). This was the primary end point. Data supplied suggest an NNT of 5, which is reasonable. It is interesting

IPSS, International Prostate Symptom Score; MCC, volume at bladder capacity; NS, not significant; PVR, postvoid residual; Qmax, maximum flow rate; VFC, volume at first contraction.

From: Blake-James BT, Rashidian A, Ikeda Y, et al. The role of anticholinergics in men with lower urinary tract symptoms suggestive of benign prostatic hyperplasia: a systematic review and meta-analysis. *BJU Int* 2007;99:85–96.

to note that neither drug used alone was significantly better than placebo in terms of patient perception of benefit, although the tamsulosin arm showed IPSS improvement (Fig. 104-12). There were only minor adverse events, which were equally distributed in the groups.

The data suggest that in this population of men with LUTS but enriched by recruitment of men with OAB symptoms (24% reported episodes of incontinence at baseline, for instance), a treatment strategy targeting both the bladder and the prostate was needed for maximal benefit to be achieved. Kaplan and colleagues (2006) postulate that the best candidates for this form of combination therapy might be those men not immediately responding adequately to α -blocker therapy alone.

Once again, the added expenses of combination therapy need to be considered, although the NNT rate is encouraging. In a study using pooled data from two large, phase 3, double-blind RCTs in men with OAB, it was shown that trospium extended-release (XR) was safe and effective with significantly reduced frequency and urgency incontinence but was associated with two episodes of retention (2.1%), both in men older than 75 years (MacDiarmid et al, 2011).

The benefits of flexible-dose fesoterodine were tested in a study of 943 men with residual symptoms of OAB after treatment with an α -blocker for LUTS or BPH. Although many of the outcome parameters were no better for fesoterodine than for placebo, there were significant improvements in urinary frequency and symptom bothersomeness for the fesoterodine group (Kaplan et al, 2012). Finally, a recent study of solifenacin plus tamsulosin oral controlled absorption system (OCAS) did not find significant improvement in

IPSS in the total study population but did find significant efficacy with regard to urinary frequency and voided volume and quality-of-life benefits as measured by IPSS, quality-of-life score, and Patient Perception of Bladder Condition score over tamsulosin OCAS monotherapy in men with both voiding and storage symptoms of LUTS (Van Kerrebroeck et al, 2013). Current European guidelines suggest that antimuscarinics can be added to α -blockers to address storage symptoms when monotherapy with α -blockers is inadequate (Oelke et al, 2012).

The short-term data suggest that combination of antimuscarinic and α -blocker therapy is safe with minimal risk of retention or AUR in carefully selected men. It would seem advisable to avoid treating men with a substantial residual urine (200 mL or more in most studies), and men on treatment who report increased hesitancy or who show signs of increasing PVR or clinical evidence of retention should be warned to stop the antimuscarinic element of the combination therapy immediately. Men with significant obstruction and large, persistent residual urine volumes should be considered for surgical therapy rather than the addition of antimuscarinic agents.

β_3 Agonist (Mirabegron)

Mirabegron is the first of a new class of drugs. β_3 agonists enhance bladder relaxation during bladder filling by blocking the β_3 adrenoceptors in the detrusor muscle. Mirabegron can increase bladder capacity without blocking contractility. Herschorn and colleagues (2013) reported that 25- and 50-mg doses were well tolerated and associated with significant improvements in incontinence episodes

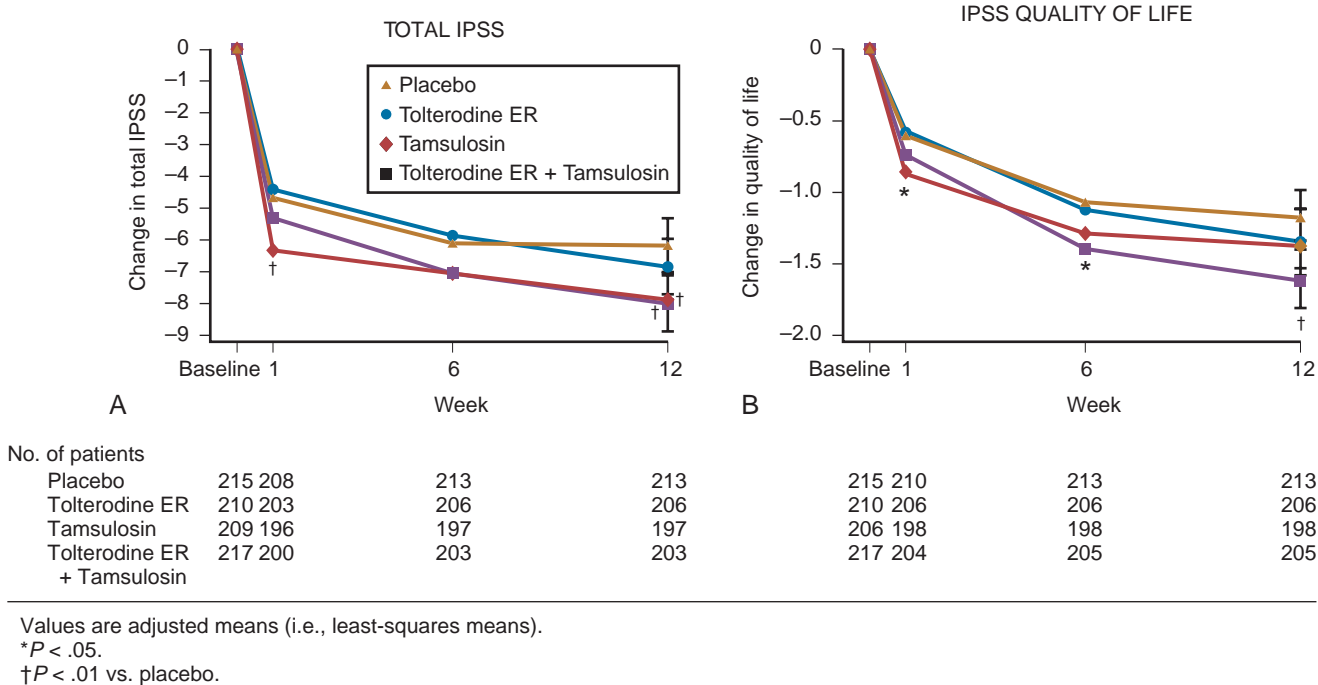

Figure 104-12. Response of lower urinary tract symptoms to tolterodine, tamsulosin, or combination versus placebo. ER, extended release; IPSS, International Prostate Symptom Score. (From Kaplan SA, Roehrborn CG, Rovner ES, et al. Tolterodine and tamsulosin for treatment of men with lower urinary tract symptoms and overactive bladder: a randomized controlled trial. *JAMA* 2006;296:2319–28.)

and micturition frequency. Mirabegron has now received regulatory approval in Japan, the United States, and much of Europe. See Chapter 77 for more detail.

PHOSPHODIESTERASE INHIBITORS

The rationale for the use of PDEIs in the treatment of LUTS and BPH was initially based on demographic data showing the frequent occurrence of both ED and LUTS in men as they age (Table 104-12). This raised the possibility of a common underlying mechanism at least contributing to both processes, which in turn raised the possibility of new treatment options that might affect both processes. After the first clinical report in 2002 of improvement in LUTS in men given sildenafil (Viagra) for their ED (Sairam et al, 2002), there has been growing interest in the role of PDEIs as treatments for LUTS and in particular for the management of the many men with both conditions, who are commonly found in our clinics. The scientific basis is rapidly becoming stronger, and there is now good level 1 evidence from multiple clinical trials clearly showing improvement of LUTS after treatment with a range of PDEIs versus placebo (McVary et al, 2007a, 2007b; Roehrborn et al, 2008b; Stief et al, 2008; Porst et al, 2011) (Table 104-13) or versus tamsulosin (Oelke et al, 2012). However, in the studies so far available, there have been no significant changes in Qma, suggesting that the effects of PDEIs alone may be either more focused on bladder muscle function than on prostatic tissue or that the effects are more profound on storage symptoms than on bladder outflow obstruction itself. The relationship between the management of LUTS and ED has been well reviewed (Kohler and McVary, 2009). ED is commonly found in men who are at risk for LUTS. This association is found throughout the western world as well as in Asian studies. The pathophysiologic link between these conditions is not yet clear, but several theories have been described with various levels of supporting data (Fig. 104-13). It is likely that there is an overlap between the roles of each of these candidate mechanisms, and an ultimate effect leading to smooth muscle relaxation in pros-

tatic, bladder neck, or erectile tissues appears to be crucial. Candidate mechanisms include the following:

1. *Pelvic atherosclerosis.* The pelvic atherosclerosis theory suggests that just as penile ischemia leads to smooth muscle loss in the penis, so smooth muscle damage in the bladder would decrease compliance and predispose to replacement of bladder smooth muscle with collagen and fibrosis. Reduced nitric oxide synthase (NOS) expression is seen with ischemia. Furthermore, conditions promoting pelvic atherosclerosis such as hypertension, smoking, hypocholesterolemia, and diabetes mellitus are implicated in both ED and LUTS.
2. *Autonomic hyperactivity.* Autonomic hyperactivity and particularly increased sympathetic tone is seen in various components of the metabolic syndrome and has been implicated in the development of LUTS (McVary, 2005).
3. *The calcium-independent Rho/Rho-kinase activation pathway.* Abnormal activation of the Rho/Rho-kinase pathway is involved in the pathogenesis of hypertension, vasospasm, and arteriosclerosis and is a potent target of new therapies for these diseases. RhoA/Rho-kinase may suppress endothelial nitric oxide synthase (eNOS). Rho-kinase appears to play a key role in the regulation of force and velocity of actomyosin cross-bridging in smooth muscle by inhibiting myosin phosphatase-mediated dephosphorylation of the regulatory chain of myosin II. This calcium-independent pathway leads to smooth muscle contraction, probably by creating mediators of α adrenergic (nor-epinephrine) and endothelin-1 (ET-1) promoted smooth muscle contraction. Abnormal Rho-kinase activation or upregulation contributes to a lack of smooth muscle relaxation in the urinary tract and thus to changes in bladder compliance and to LUTS.
4. *Reduced nitric oxide levels* (probably the best explored process so far). Nitric oxide is a nonadrenergic, noncholinergic (NANC) mediator of smooth muscle activity. Burnett and coworkers (1995) reported NOS activity in the prostate. Takeda and associates (1995) showed prostate smooth muscle tension is mediated by nitric oxide. NO activates soluble guanylate cyclase (sGC) of smooth muscle cells, which in turn increases cyclic guanosine monophosphate

TABLE 104-12 Summary of Epidemiologic Studies Associating Lower Urinary Tract Symptoms (LUTS) with Erectile Dysfunction (ED)

STUDY	STUDY DESIGN OR NAME	N	FINDINGS
Braun et al, 2000	Cologne Male Survey	4000	LUTS in 72.2% of patients with ED vs. 37.7% without ED; prevalence risk highly significant.
Blanker et al, 2001	Krimpen Community Cohort	3924	ED RR: 1.8-7.5 for increasing urinary complaints; risk of ED greater with LUTS than with smoking or cardiac symptoms.
Moreira et al, 2003	Brazilian Cohort Study	428	ED incidence RR: 3.67 if self-reported BPH—2-yr follow-up; addresses temporality of BPH → ED.
Boyle et al, 2003	UrEpik study	4800	IPSS >7 showed odds ratio of 1.39 of having ED in a weighted multiple regression model, including age; similar odds ratios: heart attack, hypertension, and smoking.
Vallancien et al, 2003	Cross-Sectional European Survey	1274	55% of patients with mild LUTS had ED vs. 70% with severe LUTS; significance maintained after multiple regression analyses.
Rosen et al, 2003	Multinational Survey of the Aging Male	12,815	RR 3.7-7.6; IPSS correlated with IIEF, sexual activity, and ejaculatory parameters; controlled for age and comorbidities; older men still sexually active.
Braun et al, 2003	Cologne Male Survey	4489	Prevalence of LUTS in men with ED was about 72.2% (n = 621) vs. 37.7% (n = 1367) in men with normal erections; the odds ratio was 2.11, even after controlling for age.
Chung et al, 2004	Cross-Sectional Community Survey	2115	LUTS correlated with ED; sexual satisfaction and libido inversely correlated with LUTS.
Ponholzer et al, 2004	Austrian study	2858	RR for ED in men with LUTS (IPSS >7) was 2.2; controlled for age, vascular risk factors, and predominance of obstructive or irritative symptoms.
Hansen, 2004	Danish study	3442	LUTS predicted ED after multiple regression; RR 2.3-3.4; overall LUTS prevalence 39% and ED prevalence 29%.
Elliott et al, 2004	U.S. Veterans Administration Survey	181	ED correlated with obstructive LUTS after controlling for age, depression, hypertension, and coronary artery disease on multivariate analysis.
Terai et al, 2004	Japanese Cross-Sectional Survey	2084	RR: 1.5; ED correlated with LUTS (IIEF vs. IPSS); correlation remained after controlling for age.
McVary et al, 2004	MTOPS Secondary Analysis	3000	AUASS correlated with ED and other domains; included correlation with maximum flow rate (multivariate analysis controlled for confounders).
Shiri et al, 2005	Finnish Cohort Study	1126	RR of ED incidence with DAN-PSS score 7-11 was 2.7, RR was 3.1 for DAN-PSS >12 over a 5-yr period; addresses temporality of BPH → ED.
Paick et al, 2005	PLESS study and Questionnaire	2981	2% increase in ED risk for unit increase in PLESS LUTS survey, significant after controlling for age.
Brookes et al, 2008	BACH Study Subset Analysis	2301	Multivariable regression model of ED found strong association of AUASS and ED independent of age; nocturia, incontinence, and prostatitis strongest factors; no differences found across race or ethnicity.

AUASS, American Urological Association symptom score; BACH, Boston Area Community Health; BPH, benign prostatic hyperplasia; DAN-PSS, Danish Prognostic Symptom Score; IIEF, International Index of Erectile Function; IPSS, International Prostate Symptom Score; MTOPS, Medical Therapy of Prostatic Symptoms trial; PLESS, Proscar Long-Term Efficacy and Safety Study; RR, relative risk.

(cGMP) levels. This in turn is responsible for smooth muscle cell relaxation and penile erection, for instance. This process is most likely to involve activation of potassium channels by cGMP leading to hyperpolarization and closure of voltage-dependent calcium channels. Intracellular levels of calcium are reduced with an effect on myosin and its detachment from actin and muscle relaxation.

Clinical investigation really began in 2000 with a study of 112 men being studied for their response to sildenafil but whose urinary symptoms were also prospectively assessed by IPSS and measurement of Qmax over a 3-month period (Sairam et al, 2002). This open-label descriptive study was the first study to measure parameters of both ED and urinary symptoms and showed an

improvement in LUTS as well as ED in response to sildenafil. Similar smaller studies were followed by RCTs using sildenafil, tadalafil, and vardenafil (McVary et al, 2007a, 2007b; Roehrborn et al, 2008b; Stief et al, 2008). These initial trials are summarized in Table 104-13. Other PDEIs (udenafil, UK-369003 [Tamimi et al, 2010], mirodenafil) have also shown efficacy in trials.

The first RCT published that elucidated the impact of PDEIs on LUTS was by McVary and colleagues (2007a). This was the first proper randomized controlled study and was a 12-week double-blind placebo-controlled investigation performed in 41 centers in the United States between March 2004 and May 2005. Men with both ED (scoring lower than 25 on the International Index of Erectile Function [IIEF]) and LUTS (scoring higher than 12 on IPSS)

Modified from Giuliano F, Ückert S, Maggi M, et al. The mechanism of action of phosphodiesterase type 5 inhibitors in the treatment of lower urinary tract symptoms related to benign prostatic hyperplasia. *Eur Urol* 2013;63:506–16.

with no evidence of prostate cancer were enrolled; 369 men in total were randomized between sildenafil (189 men) and placebo (180 men). They were assessed according to a range of other parameters (e.g., BPH Impact Index, quality-of-life score, self esteem and relationship questionnaire) and, as expected, men's ED improved. However, their IPSS and other urinary symptom scores improved as well. IPSS improved by 6.32 points compared with 1.93 for placebo. BPH Impact Index score improved by 2 points compared with 0.9 for placebo, and the quality-of-life score improved by 0.97 compared with 0.29 for placebo. It is interesting to note that men with more severe LUTS improved more (by 8.6 compared with 2.4 in the less severely symptomatic men). **There was no significant difference in Qmax, which led the authors to suggest that possibly other mechanisms were involved than simply smooth muscle relaxation in the bladder and prostate.** They pointed out that other phosphodiesterases were present in the prostate, particularly types 4 and 11, and that these may have a part to play.

In answer to questions raised about this study, more information was subsequently provided regarding baseline IPSS scores. These data showed baseline IPSS scores of 20.76 (± 5.6) for those randomized to sildenafil and 20.55 (± 5.5) for those randomized to placebo. The sildenafil group improved by 6.32 points compared with 1.93 for the placebo arm. The subsequent data also indicated that the

improvement in IPSS score was greater in those men whose ED also responded—that is, an IPSS improvement of 7 versus 3.2 in those whose ED did not respond ($P < .0001$).

The second RCT (McVary et al, 2007b) investigated tadalafil. This study was designed to establish a proof of principle before larger and more definitive trials. It was a double-blind, placebo-controlled, randomized multicenter study in 21 centers in the United States. It included first a 4-week washout phase, but also a 4-week single-blind placebo run-in period before determination of baseline values and compliance, to reduce the placebo effect and the reversion to the mean phenomenon. Then followed the double-blind phase, randomizing men between tadalafil and placebo. Men in this study were chosen on the basis of their urinary symptoms (men over 45 with LUTS by IPSS of 13 or higher and a Qmax of 4 to 15 mL/sec, PSA level below 10, and PVR less than 200 mL). They were randomized to placebo or tadalafil at 5 mg for 6 weeks, after which the dose was escalated to 20 mg daily for a total of 12 weeks. The study ran between November 2004 and July 2005. As before, a range of parameters were measured. Of 281 men, 138 were randomized to tadalafil and 143 to placebo. There was a moderate response at 6 weeks, but a greater difference between the two arms by 12 weeks. Baseline IPSS scores in the tadalafil arm improved by 3.8 points, whereas the placebo arm baseline IPSS of 18.3 improved by 1.7

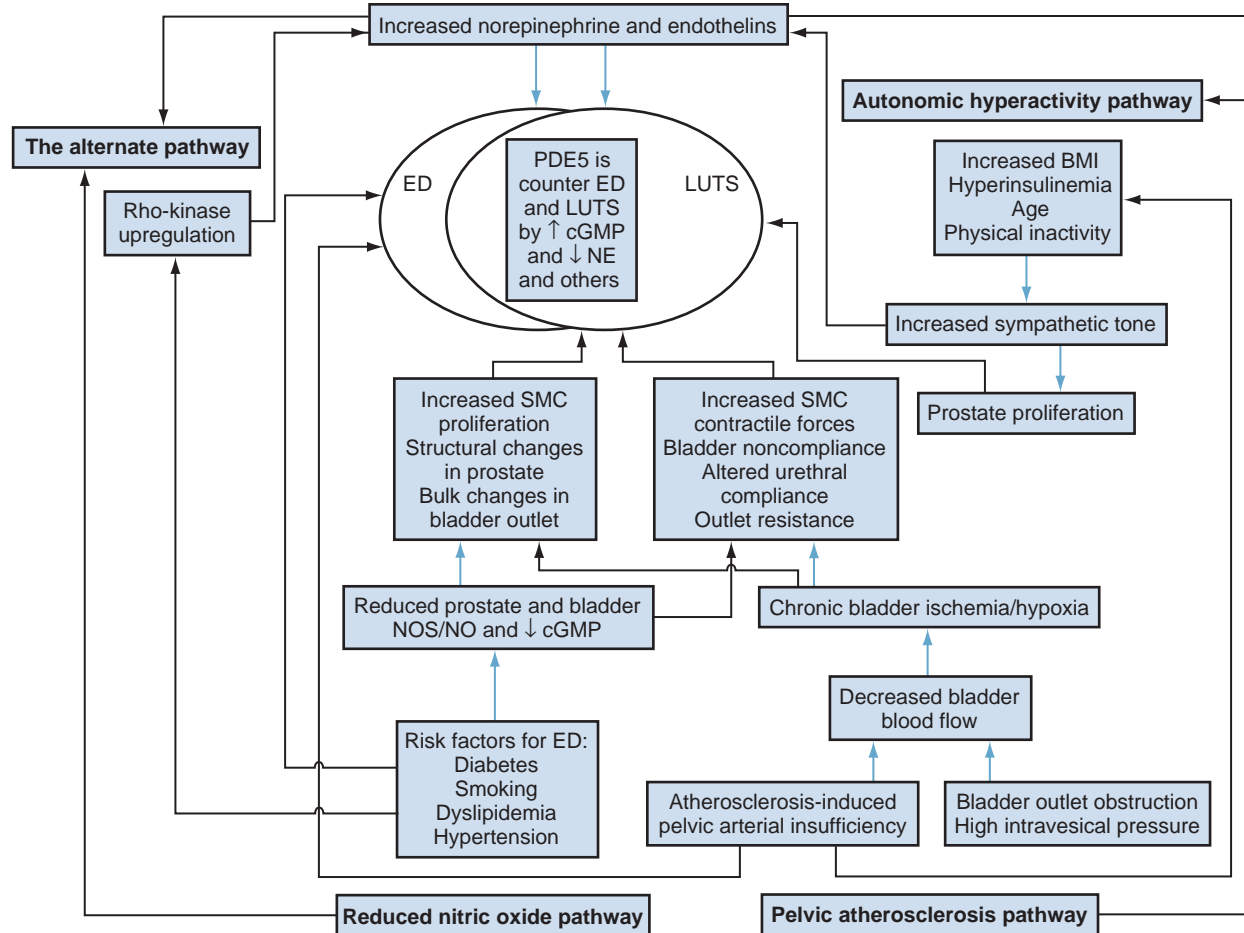

Figure 104-13. Theories linking pathophysiology of erectile dysfunction (ED) and lower urinary tract symptoms (LUTS). points; $P < .001$, thus indicating a net improvement of 2.1 points for the active arm. Whether a 2-point change is clinically significant or easily perceived by men is uncertain, but it is comparable to the response to α -blocker treatment in the meta-analysis performed by the AUA BPH guideline update panel (McVary et al, 2006, 2011). If the placebo run-in period is included, then the active-arm response of 7.1 points on IPSS (± 0.6) is similar to that in the sildenafil study (6.32 points). More convincingly, men in the tadalafil group were more likely to show a 3-point or greater improvement in IPSS by 12 weeks than men in the placebo group (60.9% vs. 42.7%), indicating an NNT of 5.5, which is seen as reasonable and representing effective therapy (Bandolier, 2003).

Roehrborn and coworkers (2008b) built on this proof of principle experience with a dose-finding study—a larger study of 1058 men performed in 92 centers in 10 countries. Men were randomized to placebo or 2.5, 5, 10, or 20 mg of tadalafil once daily. This randomized, double-blind, placebo-controlled 12-week study also included a 4-week single-blind placebo run-in period (during which the IPSS of 67 men improved from the “moderate/severe” range to the “mild” category) and generally similar inclusion criteria and outcome assessments, with the IPSS response to the 5-mg tadalafil regimen being the primary outcome.

Daily administration of 5 mg of tadalafil led to a statistically significant net improvement of 2.6 points in IPSS compared with placebo (4.87 vs. 2.27), again similar to α -blocker responses. Most of the response was seen by 8 weeks, and there was minimal further improvement at the higher doses (Fig. 104-14). There was no

significant change in Qmax at any dose, nor were there changes to PSA or PVR.

Stief and colleagues (2008) investigated vardenafil in a similar fashion in a randomized, double-blind, placebo-controlled phase 2b study undertaken in 16 centers in Germany between October 2005 and June 2006. Men were randomized to vardenafil 10 mg twice daily (109 men) and placebo (113 men) and assessed at 4 and 8 weeks. This was another proof-of-concept study and did not include a placebo run-in period. Eventually 105 men took vardenafil and 110 placebo. Vardenafil was associated with a significant improvement in IPSS versus placebo. IPSS score improved from 16.8 to 11 (or by approximately 5.9) with vardenafil compared with 16.8 to 13.2 (3.6) on placebo—that is, a mean difference of 2.3 points, again similar to an α -blocker response to alfuzosin or tamsulosin. There were small but not significant improvements in Qmax (15.9 to 17.5 mL/sec). This was a relatively young cohort and had reasonable Qmax values at baseline, so a study with older men and lower flow rates might more readily assess whether there is any effect of PDEIs on the flow aspects of BPH and LUTS.

Despite men reporting significant improvements in IPSS (mean difference between treatments 4.2, $P < .001$), detailed urodynamic studies (Dmochowski et al, 2010) comparing once-daily tadalafil 20 mg with placebo during a 12-week RCT showed that urodynamic measures remained largely unchanged during the study, with no statistically significant or clinically adverse difference between tadalafil and placebo in change in detrusor pressure at maximum urinary flow rate or any other urodynamic parameter assessed,

Figure 104-14. Response of lower urinary tract symptoms to tadalafil. Mean change in International Prostate Symptom Score (IPSS) and Benign Prostatic Hyperplasia Impact Index after treatment with placebo or tadalafil (Tad) at 5, 10, and 20 mg/day. (From Roehrborn CG, McVary KT, Elion-Mboussa A, Viktrup L. Tadalafil administered once daily for lower urinary tract symptoms secondary to benign prostatic hyperplasia: a dose finding study. *J Urol* 2008;180:1228–34.)

including maximum urinary flow rate, maximum detrusor pressure, Bladder Outlet Obstruction Index score, or bladder capacity. A study of urodynamics in men before and after randomization to tamsulosin 0.4 mg and the now standard-dose tadalafil 5 mg (group 1; $n = 20$) or tamsulosin 0.4 mg and placebo (group 2; $n = 20$) once daily for 30 days pdetQmax showed a significant reduction in the tamsulosin-tadalafil group (13 ± 17.0) compared with the tamsulosin-placebo group (-1.2 ± 14.35) group ($P = .03$). Qmax increased in both groups: tamsulosin-tadalafil, 1.0 ± 2.4 , and tamsulosin-placebo, 1.4 ± 2.4 (Regadas et al, 2013).

Further good-quality studies have confirmed the benefits of PDEIs. Tadalafil has become the dominant agent because of its half-life and convenient 5-mg daily dose and has now been licensed widely for prescription for male LUTS. Analysis of the pooled data of 1500 men in the four international tadalafil RCTs suggested that tadalafil showed consistent efficacy compared with placebo across multiple subgroups—for example, age, prostate volume, previous therapy, symptom severity, and presence of hypogonadism (Porst et al, 2013). Similar responses were shown in men with or without ED (Broderick et al, 2010; Brock et al, 2013) (indicating that improvement is not just because of better sexual function) and in other racial groups such as Asian men (Yokoyama et al, 2013).

Combination Therapy: α -Adrenergic Blockers and Phosphodiesterase Inhibitors

PDEIs and α -blockers in combination reduce adrenergic tone in prostate, bladder neck, and cavernosal smooth muscle tissue in

organ bath studies (Oger et al, 2009; Angulo et al, 2012), leading researchers to consider combining PDEIs and α -adrenergic blocker medication in man. So far, evidence for combination therapy with α -adrenergic blockers and PDEIs is limited. Kaplan and colleagues (2007), in a 12-week open-label single-center pilot study, randomized 62 men among 25 mg of sildenafil (21 men), 10 mg of alfuzosin (20 men), and a combination of both agents (21 men). IPSS improved by 11.8% on sildenafil (i.e., decreased from 16.9 to 14.9), by 15.6% on alfuzosin, and by 24.1% on a combination of sildenafil and alfuzosin, suggesting that there may be a synergistic benefit from the use of both agents.

Improvement in Qmax was observed in all groups, but patients receiving combination therapy had greater improvement (29.6%) than patients receiving either only alfuzosin (21.7%) or only tadalafil (9.5%). IPSS was significantly improved in the alfuzosin group (27.2%) and was more marked in the combination therapy group (41.6%). There was a small nonsignificant increase in IPSS in the tadalafil only group (8.4%).

Liguori and colleagues (2009), in a randomized, open-label, three-arm study, gave 66 men with ED and LUTS tadalafil, alfuzosin, or tadalafil and alfuzosin and found that IIEF Erectile Function domain (IIEF-EF) sexual function scores did improve with alfuzosin alone (+15%). As expected, sexual function scores were more obviously improved with tadalafil alone (+36.3%), but the greatest improvement was experienced with combination therapy (+37.6%).

Improvement in Qmax was observed in all groups, but patients receiving combination therapy had greater improvement (29.6%) than patients receiving either only alfuzosin (21.7%) or only tadalafil (9.5%). IPSS was significantly improved in the alfuzosin group (27.2%) and was more marked with the combination therapy (41.6%); a small increase, although not statistically significant, was also observed with tadalafil (8.4%).

Udenafil has been administered to 120 men with LUTS-BPH and ED (Chung et al, 2009). Men on stable α -blocker therapy for their LUTS or BPH were given 100 mg of udenafil for 8 weeks. LUTS and ED improved significantly compared with baseline (IPSS improved from 14.3 to 11.5 and IIEF improved from 11.95 to 18.32). No significant changes in blood pressure or heart rate were reported in this study or in a similar study in which mirodenafil was added to α -blocker therapy (Bang et al, 2013). This is an important issue; the concomitant use of α -blockers and PDEIs may lead to symptomatic hypotension in some patients because both are vasodilators. Clearly urologists should proceed with caution, but Lee and coworkers suggest that the combination of a phosphodiesterase type 5 inhibitor (PDE5I) with losartan, nifedipine, amlodipine, doxazosin or tamsulosin could be a safe pharmacologic strategy for physicians simultaneously treating ED and its comorbidities and increasing response rates to PDE5Is (Lee et al, 2012).

Gacci and colleagues (2012) performed a meta-analysis of 12 published reports (7 on PDE5Is vs. placebo in 3214 men, and 5 on the combination of PDE5Is and α_1 -adrenergic blockers vs. α_1 -adrenergic blockers alone, in 216 men). They concluded that use of PDEIs alone led to a significant improvement in sexual function and IPSS compared with placebo and the combination of α_1 -adrenergic blockers and PDE5Is led to a significant improvement in sexual function, IPSS, and Qmax compared with α_1 -adrenergic blockers alone.

It seems reasonable to suggest that concomitant treatment with PDEIs should be initiated only once the patient has been stabilized on his α -blocker therapy. In those patients stable on α -blocker therapy, PDEIs should be initiated at the lowest recommended starting dose. In those men already taking an optimized dose of PDEIs, α -blocker therapy should be initiated at the lowest dose. Any stepwise increase in α -blocker dose may be associated with further lowering of blood pressure in patients taking PDEIs.

Studies so far suggest that vardenafil may be administered at any time with tamsulosin, whereas men given vardenafil and terazosin at the same time are more prone to hypotension. This effect was minimized by giving vardenafil and terazosin at doses separated by a time interval of 6 hours. The coadministration of doxazosin (4

and 8 mg daily) and tadalafil (5 mg daily or 20 mg as a single dose intermittently) leads to further blood pressure lowering, and this combination is not recommended.

Conclusions

PDEIs will have a role in LUTS and BPH. There is now good level 1 evidence of a beneficial effect of PDEIs on urinary symptoms. The mechanisms of effect are still unclear but the subject of extensive research because so many other body systems are also affected. It is likely that PDEI treatment will be valuable, especially for men with LUTS and significant ED. Recent U.S. data indicate that the proportion of men reporting moderate or severe LUTS ranges from 8% in those 30 to 39 years old to 26% in those 70 to 79 years old, and the prevalence of ED is also high and increases dramatically with age, with 10% of 30- to 39-year-old and 59% of 70- to 79-year-old men reporting mild-to-moderate or moderate-to-severe symptoms—clearly a substantial number of men who may request treatment (Brookes et al, 2008). It is now well recognized that patients with LUTS should be questioned about also having ED, and likewise patients with ED should be asked about concomitant LUTS (Kirby et al, 2013).

Further data on safety and cost-effectiveness, especially for combination therapy, are needed. Currently PDEIs are more expensive than α -blockers or 5 α -reductase inhibitors, which are now off patent protection in many countries and health care systems. Studies are needed to determine if costs may be reduced by using combination therapy initially followed by later withdrawal of the more expensive agent.

KEY POINTS: PHOSPHODIESTERASE INHIBITORS

- There is an as yet undetermined link between LUTS-BPH and ED.
- PDEIs improve urinary symptoms scores.
- PDEIs alone do not improve flow rates.
- The combination of α -adrenergic blockers and PDEIs may lead to a synergistic benefit, thereby improving LUTS and flow rates.
- The combination of α -adrenergic blockers and PDEIs may lead to symptomatic hypotension.
- PDEIs or a combination of α -adrenergic blockers and PDEIs may be of value in therapy for men with both ED and LUTS.

PHYTOTHERAPY

The pharmacologic use of plants and herbs (phytotherapy) for the treatment of LUTS and BPH is common. Phytotherapeutic agents for LUTS and BPH have gained widespread use since about 1990 (Lowe and Fagelman, 1999). These agents are popular in Europe, particularly in France, Austria, and Germany, where they are often prescribed and their costs reimbursed (Lowe et al, 1998). European data (Fourcade et al, 2008) show that although α -blocker monotherapy was the most frequently prescribed treatment (62.5% overall, 87.1% in Germany, 46.1% in France), phytotherapy was very popular (23.5%), followed by 5 α -reductase inhibitor monotherapy (3.75%). Combination therapy was rare. Treatment varied according to the severity of the symptoms ($P = .008$), with phytotherapy being given to patients with the lowest IPSS, and combination therapy to those with the highest IPSS. However, use in the United States has escalated. It has been estimated that over \$1 billion was spent per year in the United States alone for these products (Lowe and Fagelman, 1999). These agents have been marketed to “promote prostatic health,” and therefore it is not surprising that many men try them. Additional factors that contribute to their widespread use include being “natural” products (not “medications”), presumed safety, ease of accessibility (no prescription

BOX 104-1 Components of Plant Extracts

PHYTOSTEROLS

- β-Sitosterol
- Δ5-Sterol
- Δ7-Sterol
- Stigmasterol
- Campesterol

PHYTOESTROGENS

- Coumestrol
- Genistein (isoflavone)
- Flavonoids
- Fatty acids
 - Free
 - Esterified

TERPENOIDS

- Lectins
- Polysaccharides
- Aliphatic alcohols
- Plant oils

necessary), and their roles in avoidance of prostate surgery and prevention of prostate cancer (falsely assumed). The widespread availability of these products in health food stores, vitamin shops, traditional pharmacies, and supermarkets, as well as on numerous websites on the Internet, has contributed to their use and reflects the demand for these phytotherapeutic agents.

Origin of Phytotherapeutic Agents

Phytotherapeutic products are not the actual plant but are extracts derived from the roots, the seeds, the bark, or the fruits of the various plants used (Table 104-14). Although single plant preparations are available, many companies manufacture combination products (two or more plant extracts) in an attempt to provide “enhanced” efficacy (never proven), to improve marketability, and to provide a unique product that can be registered because there is no patent protection for these products. Only the monopreparations are evaluated and reviewed here.

Composition of the Phytotherapy Extracts

The composition of plant extracts is very complex. They contain a wide variety of chemical compounds, which include phytosterols, plant oils, fatty acids, and phytoestrogens (Box 104-1). Which of these is the active component is not clear. Both the free fatty acids and the sitosterols have been thought to be the active components.

BOX 104-2 Suggested Mechanisms of Action of Plant Extracts

Inhibition of 5 α -reductase
 Anti-inflammatory action
 Interference with growth factors
 Antiandrogenic effects
 Estrogenic effects
 Inhibition of aromatase
 Decrease of sex hormone-binding globulin
 Alteration of cholesterol metabolism
 Action on α -adrenergic receptors
 Free radical scavenging
 Alteration of lipid peroxidation
 Modulation of prolactin-induced prostatic growth
 Protection of bladder and detrusor function
 Placebo effect

Most of the plant extracts are unique. First, the plants are not identical, owing to natural variability. Second, the extraction processes used by the various manufacturers are frequently different and use various substrates for the process. Thus, even if the phytotherapeutic compounds produced by two different companies contain the same plant, the exact composition of the final products is probably different and the content of the “active” component in each preparation may also be different. For example, analysis by ConsumerLab of free fatty acid content in 27 different saw palmetto products showed variability from 0% to 95%, with only 17 containing more than the presumed standard amount of 85% (ConsumerLab, 2000). There is minimal adulteration of “BPH” herbal preparations with α -blockers or 5 α -reductase inhibitors (Elterman et al, 2010).

Mechanism of Action

In general, the mechanisms of action of the phytotherapeutic agents are unknown (Lowe et al, 1998). Many in vitro experimental studies have been undertaken to elucidate this; thus, there are numerous proposed mechanisms of action (Box 104-2). Almost all these studies use supraphysiologic doses that are many times higher than the standard doses used clinically. The biologic effects are typically examined in tissue culture, which might not be an accurate reflection of in vivo effects (Lowe and Ku, 1996). The three mechanisms of action that have received the greatest attention are anti-inflammatory effects, 5 α -reductase inhibition, and growth factor alteration.

The anti-inflammatory effects are modulated by effects on prostaglandin synthesis. Plant flavonoids are inhibitors of both cyclooxygenase and lipoxygenase enzymes (Bach and Walker, 1982; Buck, 1996). Flavone, a phytoestrogen commonly found in plants and herbs, has been shown to be a strong inhibitor of cyclooxygenase (Mower et al, 1984; Alcaraz and Ferrandiz, 1987). *Serenoa repens* (Permixon) has been shown to inhibit phospholipase A₂ activity, thereby decreasing arachidonic acid metabolites and prostaglandin E₂ synthesis (Plosker and Brogden, 1996). In addition, in two different studies, Paubert-Braquet and colleagues (1994, 1997) demonstrated inhibition of the production of lipoxygenase metabolites and leukotrienes by neutrophils by *S. repens* and *Pygeum africanum* (Tadenan).

The most widely suggested mechanism of action of *S. repens* is as a 5 α -reductase inhibitor (Plosker and Brogden, 1996), reducing the conversion of testosterone to DHT and potentially leading to reduction of prostate volume (Gormley et al, 1992). Although inhibition of 5 α -reductase activity by *S. repens* was found in some experimental models (Sultan et al, 1984), other in vitro and in vivo data have not confirmed this effect (Rhodes et al, 1993; Weisser et al, 1996).

Two ex vivo experiments have demonstrated conflicting results. Pretreatment with *S. repens* for 3 months before suprapubic prostatectomy demonstrated a decrease in prostatic DHT and an increase in prostatic testosterone concentrations compared with controls, which suggests inhibition of 5 α -reductase activity (Di Silverio et al, 1998). In a similar pretreatment study using *Sabal serrulata* (IDS-89) for 3 months, prostate tissue levels of 5 α -reductase, 3 α -hydroxysteroid, and 3 β -hydroxysteroid oxidoreductase were not different compared with placebo (Weisser et al, 1996). An in vivo experiment of healthy male volunteers demonstrated a reduction of serum DHT levels with finasteride but not with *S. repens* (Strauch et al, 1994). Clinically, in a large multicenter trial comparing *S. repens* with finasteride, no effect on PSA levels and only a 6% reduction in prostate volume were noted for *S. repens*-treated patients, whereas the finasteride-treated patients had reduction of PSA levels by 41% and prostate volume by 18% (Carraro et al, 1996).

S. repens causes disruption of nuclear membrane in cell culture but has no effect on the integrity of the cell membrane (Bayne et al, 1999); therefore, the intracellular theory has been promulgated. Whether this supraphysiologic cell culture experiment actually reflects what is happening in vivo is uncertain and unproved.

Plant extracts are also thought to act by altering growth factor-induced growth and proliferation. In vitro studies with *P. africanum* demonstrated an inhibitory effect on both basic fibroblastic growth factor (bFGF)- and EGF-induced human and rat prostate fibroblast proliferation (Paubert-Braquet et al, 1994; Yablonsky et al, 1997). Subsequent experiments with *S. repens* have also shown inhibition of bFGF- and EGF-induced proliferation of human BPH prostate cells from biopsy specimens (Paubert-Braquet et al, 1998). In addition, an ex vivo experiment in men treated with *S. repens* before prostatectomy demonstrated reduced levels of tissue EGF, particularly in periurethral tissue (Di Silverio et al, 1998).

Although experimental data have suggested numerous possible mechanisms of action for the phytotherapeutic agents, it is uncertain which, if any, of these proposed mechanisms is responsible for the clinical responses.

***Serenoa repens* (Saw Palmetto Berry)**

The extract of the berry of the American saw palmetto, or dwarf palm plant, *S. repens* (also known by its botanical name of *S. serrulata*), is the most popular phytotherapeutic agent consumed for LUTS and BPH. Although numerous clinical trials with saw palmetto berry extracts have been published, many were uncontrolled open-label studies, which provides little useful information in determining the efficacy of these phytotherapies. Even though placebo-controlled studies have been published, most of them are flawed and none of them would meet the generally accepted criteria developed by the International Consultation on BPH for assessing treatment results in men with LUTS (Denis et al, 1998). Previous studies were of limited value because of their small numbers of patients, short duration (only 1 to 3 months), and lack of use of standardized symptoms scores. For example, nocturia was the only symptom available for analysis in all the studies reviewed in two meta-analyses (Wilt et al, 1998; Boyle et al, 2000). In the meta-analysis by Wilt and colleagues (1998) of 18 trials involving 2939 patients using various *S. repens* monopreparations and combination products, the mean weighted difference for nocturia between patients and individuals taking a placebo was -0.76 times per evening (-1.22 to -0.32) for 10 trials. In the meta-analysis by Boyle and coworkers (2000) of 13 trials involving 2859 patients using only the Permixon brand of *S. repens*, the attributable reduction of nocturnal urinations was 0.50 (± 0.01) times per night. Wilt and coworkers conducted a systematic review, first published in 1998 and updated in 2002, 2009, and again in 2012 (MacDonald et al, 2012) to evaluate the efficacy and adverse events of *S. repens*. Initially their analysis was mildly supportive of the efficacy of *S. repens*. In the 2009 update, 9 new trials involving 2053 additional men (a 64.8% increase) were included. For the main comparison—*S. repens* versus placebo—3 trials were added with 419 patients and 3 end points (IPSS, peak urine flow, prostate size). Overall, 5222 patients

BOX 104-3 Inherent Weaknesses of Meta-Analyses

Pooled results incorporate biases of individual studies
 New sources of biases created
 Incomplete selection of studies
 Publication bias (only positive trials usually published)
 Language bias
 Heterogeneity of the studies
 Inclusion or exclusion criteria
 Poor study designs
 Poor assessments of efficacy
 Variable placebo response rates
 Short study durations

from 30 randomized trials lasting from 4 to 60 weeks were assessed. Twenty-six trials were double blinded, and treatment allocation concealment was adequate in 18 studies. With these extra data and especially the double-blind, placebo-controlled trial reported by Bent and coworkers (2006), Tacklind and colleagues (2009) concluded that *S. repens* was not superior to placebo in improving IPSS or Qmax or for reducing prostate size. For nocturia, *S. repens* was significantly better than placebo (weighted mean difference -0.78 nocturnal visits, 95% CI -1.34 to -0.22 , $P < .05$) in 9 short-term Permixon trials but not in a high-quality trial. *S. repens* was also not superior to finasteride or to tamsulosin. Overall, the latest analysis (MacDonald et al, 2012) concluded that *S. repens* therapy does not improve LUTS, Qmax, or nocturia compared with placebo in men with BPH, even at double and triple the usual dose.

Despite inherent weaknesses in meta-analyses (Box 104-3), these analyses attempt to maximize the information available from clinical trials using *S. repens* in the treatment of symptomatic BPH and LUTS and to provide the best information available until the appropriate placebo-controlled, randomized clinical studies are conducted. However, approximately 35% of the prior meta-analyses performed are not reproduced in subsequent RCTs (LeLorier et al, 1997). Current meta-analysis suggests that *S. repens* is not more effective than placebo for treatment of LUTS. The Complementary and Alternative Medicine for Urological Symptoms (CAMUS) study was set up to address these deficiencies and concluded that increasing doses of a saw palmetto fruit extract did not reduce LUTS more than placebo (Barry et al, 2011) and did not affect serum PSA more than placebo, even at relatively high doses (Andriole et al, 2013) but did appear safe (Avins et al, 2013).

Pygeum africanum (African Plum)

In addition to the proposed mechanisms of actions previously discussed, *P. africanum* has been postulated to have additional beneficial effects on LUTS by having a protective effect on the obstructed bladder. Using a rabbit model with partial BOO, Levin and associates (1996) demonstrated that changes in bladder mass, decrease in compliance, and alterations in contractile response to various forms of stimulation could be tempered by pretreatment with *P. africanum*.

A review of the published experience with *P. africanum* (Tadenan) identified 2262 patients treated with this extract: 1810 in open-label studies and 452 in comparative trials (Andro and Riffaud, 1995). Twelve double-blind, placebo-controlled studies were completed from 1972 to 1990. Only one study enrolled more than 100 patients, and none was longer than 12 weeks or used standardized symptom scores. A 2-month open-label study (Breza et al, 1998) and a 2-month comparison trial of 50 mg twice daily versus 100 mg daily (Chatelain et al, 1999) both demonstrated a reduction in IPSS score of approximately 40% (5.7 and 6.4 units) and an improvement in PFR of approximately 18% (2.1 and 1.7 mL/sec) over baseline. However, without a placebo arm, the actual magnitude of drug effect cannot be determined. Thus, without at least the data from the Tadenan-IPSS study, the efficacy of *P. africanum* cannot be determined. In addition, there are few other significant data

available with regard to any of the other *P. africanum* extracts. Thus, none of those trials meets the guidelines recommended by the International Consultation conferences on BPH. Another meta-analysis for the Cochrane collaboration (Wilt et al, 2002a) concluded that an effect was possible but not proven. Therefore the data concerning the efficacy of *P. africanum* are not conclusive.

Hypoxis rooperi (South African Star Grass)

Hypoxis rooperi (Harzol) has been studied in both a 6-month double-blind, placebo-controlled trial of 200 patients (Berges et al, 1995) and, subsequently, an open-label follow-up (Berges et al, 2000). In the initial study, statistically significant improvements were documented for symptom scores (IPSS), quality of life, PFRs, and PVRs (Berges et al, 1995). The placebo group showed appropriate mild improvement in these parameters. The IPSS improved by 7.4 units for β -sitosterol patients and 2.3 units for placebo. Similarly, peak urinary flow rates improved by 5.2 mL/sec for treated patients compared with 1.1 mL/sec for placebo. **This magnitude of improvement has not been observed with any other medical therapy previously evaluated for LUTS/BPH.**

During the follow-up study, patients were able to remain on or switch over to Harzol therapy. For those 38 patients who continued Harzol therapy, IPSS improvements were maintained. The 27 patients who received placebo initially and were then treated with Harzol demonstrated similar levels of improvement in IPSS scores and PFRs. Surprisingly, the 14 patients who stopped therapy still maintained similar levels of improvement over the next 12 months. This suggests that intermittent therapy could be an option.

Another product (Azuprostat) contains primarily β -sitosterols from *H. rooperi* as well as from *Pinus* (pine) and *Picea* (spruce). Although this is a combination preparation of extracts, its proposed active ingredient, β -sitosterol, is common to all three. This product (Azuprostat) was evaluated in a 6-month randomized, placebo-controlled trial with 177 patients (Klippel et al, 1997). Significant improvements in IPSS scores, PFRs, and PVRs were found. IPSS scores improved by 8.2 units for treated patients and 2.8 units for placebo. PFRs improved by 8.9 mL/sec for treated patients and 4.4 mL/sec for placebo. This magnitude of improvement has not been reported for any type of medical therapy for LUTS or BPH. It is hard to believe these results, in which the mean post-treatment PFRs are 19.4 mL/sec—a normal value for younger men and not for the typical age of men in the study. If these results are reproducible, they would rival the results of surgical intervention.

Wilt and associates (1999) also produced a meta-analysis for β -sitosterol products. It included four trials (two mentioned earlier and two earlier suboptimal ones) encompassing three different products: Harzol, Azuprostat, and WA184, all of which have different amounts of β -sitosterol. WA184 did not improve Qmax (Kadoff et al, 1986). Again, this meta-analysis is tempered by the same factors mentioned previously. The researchers' conclusion was that **β -sitosterol does improve urologic symptoms and urinary flow rates, but its long-term effectiveness, safety, and ability to prevent the complications of LUTS/BPH are unknown (Wilt et al, 1999).**

Lycopenes and Other Extracts

Ilic and Misso (2012) in a systematic review of the eight best lycopene studies felt that it was not possible to support or refute the use of lycopene for the prevention or treatment of BPH. Isoflavones (Soylife 40) were studied in 176 men with "only slight superiority" to placebo (Wong et al, 2012). The other extracts listed in Table 104-14 (*Urtica dioica*, *Cucurbita pepo*, *Secale cereale*, and *Opuntia*) have even fewer relevant clinical studies published. Of these extracts, *S. cereale* (Cernilton) had two placebo-controlled trials published more than two decades ago that did not have standardized scores, used different doses of the preparation, lasted 12 and 24 weeks, and enrolled only 103 and 60 patients (Buck et al, 1990). Wilt and associates (1999) in a systematic review and meta-analysis of Cernilton concluded that it modestly improves overall urologic symptoms including nocturia but that additional trials are needed

to evaluate clinical effectiveness (MacDonald et al, 1999). Zhang and colleagues (2008) have reported a randomized, double-blind, placebo-controlled clinical trial of a flaxseed lignan extract containing 33% secoisolariciresinol diglucoside (SDG). SDG was evaluated for its ability to alleviate LUTS in 87 patients with LUTS and BPH, with repeated measurements conducted over a 4-month period using treatment doses of 0 (placebo), 300, or 600 mg of SDG per day. After 4 months of treatment, 78 of the 87 patients completed the study. For the 0-, 300-, and 600-mg/day SDG groups, respectively, the IPSS decreased -3.67 ± 1.56 , -7.33 ± 1.18 , and -6.88 ± 1.43 (mean \pm standard error [SE], $P = .100$, $< .001$, and $< .001$ compared with baseline), the quality-of-life score improved by -0.71 ± 0.23 , -1.48 ± 0.24 , and -1.75 ± 0.25 (mean \pm SE, $P = .163$ and $.012$ compared with placebo and $P = .103$, $< .001$, and $< .001$ compared with baseline), and the number of patients whose LUTS grade changed from “moderate/severe” to “mild” increased by 3, 6, and 10 ($P = .188$, $.032$, and $.012$ compared with baseline). Qmax insignificantly increased by 0.43 ± 1.57 , 1.86 ± 1.08 , and 2.7 ± 1.93 mL/sec (mean \pm SE, no statistical significance reached), and postvoiding urine volume decreased insignificantly by -29.4 ± 20.46 , -19.2 ± 16.91 , and -55.62 ± 36.45 mL (mean \pm SE, no statistical significance reached). The observed decreases in IPSS and quality-of-life score were correlated with the concentrations of plasma total lignans. Zhang and coworkers (2008) concluded that dietary flaxseed lignan extract appreciably improved LUTS, and the therapeutic efficacy appeared comparable to that of α_{1A} -adrenoceptor blockers and 5 α -reductase inhibitors.

Summary

Most phytotherapeutic preparations are plant extracts with different components manufactured by different extraction procedures, which prevents comparison of the preparations. Although numerous in vitro experiments have been conducted to determine their possible mechanisms of pharmaceutical action, it is uncertain which of the actions demonstrated in vitro might be responsible for clinical responses in vivo. Appropriate randomized placebo-controlled clinical trials monitored by an outside agency are needed to ascertain and to confirm the efficacy of these products. Phytotherapies for LUTS and BPH should be scrutinized and subjected to trials just as are all regulated drugs.

ACUTE URINARY RETENTION

Management of Acute Urinary Retention

AUR is the commonest urologic emergency managed by most urologists worldwide. Furthermore, it will be encountered by most physicians whatever their specialty and is commonly witnessed on surgical and elderly care wards. AUR may be spontaneous, in which case it is usually associated with previous LUTS or BPH. Alternatively, it may be precipitated by some other factor such as the effects of various medications, particularly anticholinergic or sympathomimetic agents, commonly found in cough and cold remedies. Urinary infection, excessive fluid intake, and the consequences of surgery (postoperative pain or the effects of anesthesia or analgesia or loss of mobility) may precipitate AUR. Obviously there can be an overlap between these two rather artificial divisions, and AUR in a man with symptomatic or silently progressing BPE or BOO may well be precipitated by one of these other factors.

Population-based cohort studies from the United States (Jacobsen et al, 1997; Meigs et al, 1999), from Holland (Verhamme et al, 2005), and also from the United Kingdom (Cathcart et al, 2006) defined the incidence, although it varies among populations. Verhamme and colleagues, in a study based on Dutch general practitioner records covering essentially the whole male population of Holland, reported an incidence of 2.2 AUR events per 1000 man-years, of which 40% were precipitated (Fig. 104-15). AUR was the first symptom in 49% of men designated as suffering from LUTS or BPH, and in this group the risk of AUR was 11 times higher (18.3 per 1000 man-years). They concluded that AUR was of

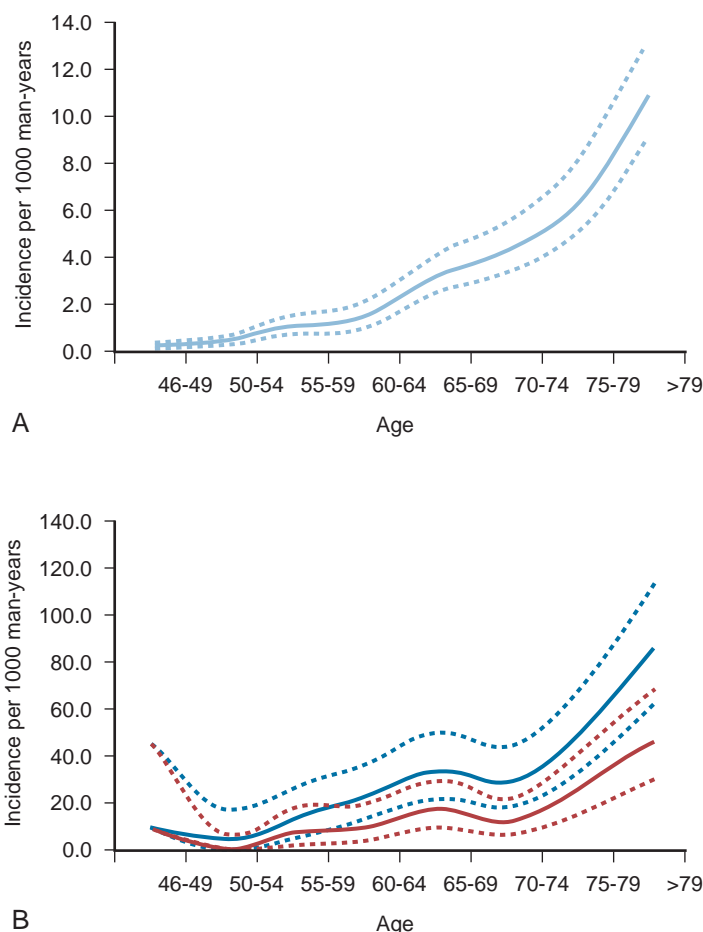

Figure 104-15. Incidence of acute urinary retention in the general population of Dutch men (A) and in the lower urinary tract symptoms and benign prostatic hyperplasia population (B). (From Verhamme KM, Dieleman JP, van Wijk MA, et al. Low incidence of acute urinary retention in the general male population: the triumph project. *Eur Urol* 2005;47:494–8.)

low incidence in the general population but substantial in the LUTS and BPH population. Cathcart and colleagues (2006), reviewing national U.K. figures, reported 3.1 AUR episodes per 1000 man-years.

These figures are lower than in the two U.S. cohort studies. Jacobsen and coworkers (1997) found an incidence of 6.8 events per 1000 man-years in the Olmsted County Study, and the Health Professionals Follow-up Study (Meigs et al, 1999) reported a rate of 4.5 per 1000 man-years. There may be selection bias here, as the prevalence of BPH and LUTS in these U.S. studies is much higher than in the European studies (33% of the Olmsted County men had an IPSS of greater than 8, and 30% of the men in the Health Professionals Study had a diagnosis of BPH or LUTS compared with just 8% in the Dutch men). Analysis of the placebo arms of a series of large studies such as the PLESS evaluation of finasteride, MTOPS, and the CombAT study indicate that increasing age, the presence of LUTS, a low Qmax, and prostatic enlargement and/or raised PSA increase the risk of AUR.

When AUR develops, most men are catheterized for a period or taught intermittent self-catheterization. At some variable point the catheter will usually be removed and a trial without catheter (TWOC) performed (Emberton and Fitzpatrick, 2008). It is reasonable to speculate that urinary retention is caused in part by dynamic as opposed to static outflow obstruction because a significant proportion of men void spontaneously after catheter removal (Taube and Gajraj, 1989). If urinary retention is caused by increased sympathetic activity at the level of the prostatic smooth

muscle, an α -blocker should increase the likelihood of spontaneous voiding after catheter removal.

The chance of successful voiding after a period of AUR was improved by the use of alfuzosin (McNeill et al, 2005) and tamsulosin (Lucas et al, 2005). In a multicenter study a total of 360 men with AUR underwent emergency catheterization and were blindly randomized to alfuzosin 10 mg once daily or placebo for 3 days (first phase). All patients with successful TWOC, regardless of treatment, were then again blindly randomized to alfuzosin 10 mg once daily or placebo for 6 months (second phase). Alfuzosin significantly increased the successful TWOC rate (146 of 236, 61.9%) compared with placebo (58 of 121, 47.9%; $P = .012$). In the second phase, 14 (17.1%) of the 82 alfuzosin-treated patients versus 20 (24.1%) of the 83 placebo-treated patients required prostate surgery, 5 (36%) of 14 versus 13 (65%) of 20 within 1 month, and 8 (57%) of 14 versus 17 (85%) of 20 within 3 months of treatment. Emergency surgery because of AUR relapse was the main cause of failure in both groups (11 [78.6%] of 14 in the alfuzosin group and 16 [80.0%] of 20 in the placebo group). Compared with placebo, alfuzosin improved the Kaplan-Meier survival rates by 9.6% ($P = .04$), 11.4% ($P = .04$), and 8.3% ($P = .20$), with surgical risk reductions of 61%, 52%, and 29% at 1, 3, and 6 months of treatment, respectively. High PSA values and the post-TWOC residual urine volume significantly increased the risk of AUR relapse and prostate surgery (McNeill et al, 2005).

An economic analysis (Annemans et al, 2005) suggests that treatment with alfuzosin before and after a successful TWOC reduces treatment costs in the first 6 months. Unfortunately, even those who succeed will have a high rate of subsequent failure to void and 80% of those who will fail do so within 6 months (Cathcart et al, 2006). At that point surgery and/or pressure-flow studies are indicated.

Medical Therapy in the Prevention of Acute Urinary Retention

Large-scale, randomized, double-blind, placebo-controlled trials of long-term duration are necessary to determine whether a medical therapy prevents a relatively uncommon event such as AUR. In the MTOPS trial, finasteride or combination therapy with finasteride and doxazosin, but not doxazosin alone, reduced the incidence of AUR (McConnell et al, 2003). Debruyne and colleagues (2004) reported data for dutasteride that suggested similar results. Because men with large prostates have on average a threefold greater chance of developing urinary retention (Jacobsen et al, 1997), enrolling men with large prostates would enhance the probability of observing an effect on AUR. The 3-year open-label prospective study of alfuzosin supported a 0.3% risk of retention (Lukacs et al, 2000). This is markedly lower than the predicted risk of developing urinary retention in an age-matched cohort of men (Jacobsen et al, 1997) but may be more a delay rather than prevention. The trial data suggest a role for 5 α -reductase inhibitor drugs in the prevention of AUR.

FUTURE STRATEGIES FOR NONSURGICAL THERAPY FOR MALE LOWER URINARY TRACT SYMPTOMS

The nonsurgical management of LUTS and BPH evolves slowly year after year with the occasional significant breakthrough. Medical therapies provide improvement over watchful waiting for most patients (Hutchison et al, 2007), but the therapeutic response to medical therapy remains less than that to prostatectomy. As Clifford and Farmer (2000) noted in a meta-analysis of α -blocker and finasteride studies, "neither finasteride nor α -blockers approach the efficacy of prostatic surgery in terms of improvement in either symptoms or flow rates"; therefore, scope exists to develop novel strategies that may be more effective than existing therapies. Since the last edition of this text, the biggest change in management has been the acceptance of the PDE5I pathway as important in LUTS management, and the use of PDE5Is alone or in combination with

α -adrenergic blockers has become an effective reality. Developing other classes of drugs to relax smooth muscle and further targeting nonprostatic factors are potential opportunities (Fig. 104-16).

Langenstroer and associates (1993) reported that human prostate contains endogenous endothelin and that endothelin elicits a very potent contraction in the human prostate. Kobayashi and colleagues (1994) have characterized the binding properties of endothelin receptor subtypes in the human prostate. The contractile response elicited by endothelin in the human prostate is not abolished by pretreatment with selective α_1 -blockers, which suggests that relaxation of prostatic smooth muscle in BPH may also be achieved by endothelin antagonists. The involvement of the inflammatory pathway in the pathogenesis of LUTS and BPH now appears fairly clear, but mechanisms to modify the inflammatory process are still in the developmental stages. Trials with agents such as cyclooxygenase-2 (COX-2) inhibitors have shown improvements in therapeutic effectiveness when combined with α -blockers (Jhang et al, 2013). Investigations of the links between metabolic syndrome, lipid metabolism, the sex-steroid environment, and the inflammatory pathways may also yield useful agents in the future. Other potentially modifying agents for LUTS include growth factors such as vitamin D₃ receptor analogues (e.g., elocalcitol), oxytocin antagonists, and modulators of the cannabinoid system (e.g., fatty acid amide hydrolase inhibitors), but these need further evaluation in clinical studies. Other compounds, such as transient receptor potential vanilloid antagonists, Rho-kinase inhibitors, purinergic receptor blockers, hexokinase inhibitors, and endothelin targeting drugs, are still at experimental stages (Füllhase et al, 2014). Over the next 5 years, LUTS and BPH treatment will become even more patient specific and is likely to become more gene based to take into account the genetic and hereditary variations in the disease, although at the moment it seems unlikely that any single gene polymorphisms will exhibit a strong enough correlation with LUTS or BPH parameters to be clinically useful in the short term (Berges et al, 2011).

Nonprostatic factors also contribute to LUTS and BPH. LUTS have a complex pathophysiology involving far more than just the prostate and the bladder, and manipulation of the other pathways that influence LUTS, such as the endocrine, renal, neurologic, and cardiovascular pathways, may yield the next significant improvement in male LUTS management. Our present understanding of the pathophysiology of LUTS and BPH is rudimentary. We must develop a greater understanding of the pathophysiology of symptoms. This knowledge will result in more effective use of existing therapies and will provide the rationale for the next generation of therapeutic modalities.

KEY POINTS: EVALUATION AND NONSURGICAL MANAGEMENT OF BENIGN PROSTATIC HYPERPLASIA

- BPH is the commonest cause of LUTS in men beyond middle age.
- Evaluation requires a history and symptom score (IPSS) and a careful physical examination including a DRE.
- Uroflowmetry and ultrasound estimation of PVR urine volume are often helpful; a PSA measurement is requested when a diagnosis of prostate cancer would alter the management of the individual patient.
- Medical therapy with either an α -blocker or (if the prostate is large) a 5 α -reductase inhibitor is now the usual first-line management of uncomplicated LUTS.
- Combination therapy with both an α -blocker and a 5 α -reductase inhibitor has been demonstrated to be the most effective means of preventing disease progression and seems likely to become the standard of care in appropriate cases.
- Antimuscarinic agents and PDEIs are useful adjuncts for men with storage symptoms or ED. The true importance of these agents will become clearer with time.

Defining Outcomes

Presurgical Factors

Specific Technologies

Conclusion

Urinary obstruction as a result of benign prostatic disease has probably been recognized to some degree since the earliest days of medicine. One of the earliest descriptions of benign prostatic hyperplasia (BPH) was offered by Morgagni in the eighteenth century (Morgagni, 1760). Early treatments for BPH centered on open procedures with both suprapubic and perineal approaches. These surgeries were often bloody and led to unacceptable mortality and morbidity. Transurethral resection of the prostate (TURP) offered another option between watchful waiting and open prostatectomy (OP), but with rudimentary equipment and an incomplete understanding of the postoperative physiology, this procedure continued to have an elevated morbidity and even mortality.

With the introduction of medical management in the 1990s, we began to see a decrease in the need for surgery to treat lower urinary tract symptoms (LUTS) related to BPH. Medical management provided a lower-risk treatment option for patients over the previously unchallenged surgical treatments, yet at a cost of lower benefit in urologic outcomes and the need for ongoing therapy. However, despite the strides made in optimal medical management, many patients still need or request additional surgical treatment.

The expanding endoscopic options including many minimally invasive surgical techniques (MISTs) allowed the practitioner to add many other treatments into the continuum between surgical approaches and medical management. Subsequently, the urologist witnessed an explosion in procedures available for the treatment of LUTS and BPH. These new technologies are often embraced with excitement; however, many do not live up to these initial expectations, which were often based on small series of patients followed for short duration.

As the pressure to accept a new technology grows with increasing marketplace competition, the urologist must be careful in embracing each new technology until the results have been thoroughly vetted. Often when new technologies or techniques are compared with the classic monopolar TURP (M-TURP), outdated data are quoted that do not reflect contemporary TURP results. In addition, there is a considerable placebo effect inherent to all LUTS-BPH treatments, and with nonrigorous study design, such as an uncontrolled single-series cohort, any inherent placebo or sham effect will be credited to the new technology.

In this chapter, we will discuss the many treatment options available to the patient and urologist for the treatment of LUTS and BPH. Special attention will be paid to advantages or disadvantages of different techniques and differences in patient outcomes. TURP held a unique position as the only endoscopic treatment for many decades, and the depth and variety of literature surrounding the procedure are impressive. This treatment is still clearly considered the gold standard, and almost any new technology inherently ends

up being compared with TURP in a randomized controlled trial (RCT) setting or by expert opinion.

EPIDEMIOLOGY AND MARKETSHARE

Marketshare

With the rise of α -blocker therapy for treatment of LUTS and BPH in the 1980s, there has been an ongoing decrease in the rates of surgical treatment for BPH. Analysis of Medicare databases at multiple points has shown this continual decrease (Lu-Yao et al, 1994; Wasson et al, 2000), with a 5% decrease per year seen between 1999 and 2005. However, in this study period between 1999 and 2005 there was a 44% overall increase in surgical treatment of BPH (all treatment options) mostly brought on by a 529% increase in thermotherapy or laser treatment (Yu et al, 2008).

The most recent installment of this series (Malaeb et al, 2012) showed an overall peak in surgical treatment for LUTS and BPH in 2005 with a subsequent 19.8% decrease until the end of the study in 2008. Throughout the entire study period, use of TURP continued to decrease, even with the introduction of the bipolar resection system. Thermotherapy and laser therapy also had an overall decrease between 2005 and 2008; the only treatment option with an increase after 2005 was laser vaporization.

Additional insight can be drawn by examining the case log of urologists undergoing certification or recertification. An examination of 3995 case logs showed that 59% of urologists performed solely TURP, with 8% performing exclusively laser procedures. The proportion of laser procedures increased from 11% of the total to 44% of the total between 2004 and 2010. While there was no difference in age between those performing exclusively TURP or any laser procedure, practitioners utilizing laser procedures were more likely to have larger case volumes. Interestingly, after 2008, the percentage differential was fairly stable between any laser procedure (44%) and standard TURP (56%), possibly indicating some saturation (Lowrance et al, 2013).

See the Expert Consult website for further details.

Epidemiology of Surgical Treatment for Benign Prostatic Hyperplasia

The prevalence of both LUTS attributed to BPH and histologic BPH increases with age. The Baltimore Longitudinal Study (Guess et al, 1990) examined 1057 men and found that "prostatism" or BPH voiding dysfunction increased progressively from 26% in the fifth decade of life to 79% in the eighth decade of life. Prevalence of symptoms related to an enlarged prostate increased from 26%

Socioeconomic factors affecting laser use and adoption were evident from analysis of payer data in Florida that examined both inpatient and ambulatory surgery discharges for laser prostatectomy or TURP. Socioeconomic areas were characterized by lowest, medium, and highest tertiles after being identified by ZIP code. A better socioeconomic environment correlated with offering laser prostatectomy and with a more rapid adoption of the technique (Schroek et al, 2013).

of men aged 40 to 49 to 46% of men older than 70 in the Olmsted County study (Chute et al, 1993).

The prevalence of the histologic evidence of BPH follows a similar correlation with age. Men in their eighth decade (82%) were more likely to have histologic evidence than men in their fourth (8%) decade in the study by Berry and colleagues (1984). The autopsy study from Robson (1964) found prevalences of histologically confirmed BPH in prostates with gross enlargement of 14%, 37% and 39%, respectively, in men 50 to 59, 60 to 69, and older than 70 years.

Increasing Age

The risk of surgery related to BPH was noted to be considerably greater for a man age 80 years than a man age 40 years in the Veterans Administration Normative Aging Study, which was carried out prospectively from 1961 to 1982 (Glynn et al, 1985). The retrospective New Haven hospital study (Lytton et al, 1968) also found an increasing incidence of surgery for BPH through the eighth decade.

Effects of Benign Prostatic Hyperplasia Medications

The successes of medical therapy for LUTS and BPH have led to the previously decreased rates of surgical management of BPH. Subsequently, patients are now older at the time of surgical intervention than they were in previous years (Vela-Navarrete et al, 2005) and frequently have an increase in medical comorbidities (Choi et al, 2012).

An interesting retrospective review of a single Canadian institution further highlighted changes in patients undergoing intervention for LUTS and BPH (Izard and Nickel, 2011). Patients who underwent TURP in the years 1988, 1998, and 2008 were compared with regard to preoperative use of BPH medications, indications for surgery, postoperative complications, and preoperative BPH-related events. Whereas TURP decreased by 60% between 1988 and 1998, an increase was noted in the percentage of total clinic patients undergoing TURP between 1998 and 2008. The indication for surgery of "failure of medical management" increased from essentially zero in 1988 to 36% in 1998 and to 87% in 2008. Troublingly, adverse preoperative BPH-related events such as acute urinary retention (AUR) and hydronephrosis were more common in 2008 than in 1988. In addition, postoperative complications and patients discharged with a catheter were more common in 2008 than 1988. This highlights the change in the type of patient who undergoes surgery and that medical therapy may be leading to a decompensated bladder and urinary tract. This is consistent with the findings of Flanigan and colleagues (1998), who found that patients who underwent immediate TURP had a more significant improvement in peak flow rates and symptom scores than men who underwent an extended period of watchful waiting. It appears that there is a consequence to the delay in effective treatment for many men. However, baseline characteristics of men who have significant deterioration in voiding without treatment have not been defined.

Prostate Size

Despite an overall lack of correlation between prostate size and bladder outlet obstruction (BOO), a correlation does seem to exist between prostate volume and the decision for surgical intervention. Although the data came from a period before medical treatment, Berry and coworkers (1984) did find a correlation between prostate size and the decision for surgical intervention. More contemporary data on the correlation between prostate size and need for surgery are sure to be skewed by multiple factors. The now common use of 5 α -reductase inhibitors (5ARIs) will decrease both prostate size and the risk for surgery (McConnell et al, 1998; Roehrborn et al, 2002), suggesting that smaller glands are less likely to need treatment.

However, any other large conclusion on an increased prostate size leading to surgery may have been contaminated by the use of the other class of BPH treatments. Although not altering prostate gland size, α -blockers allow for the relief of symptoms while

the overall prostate growth continues unchecked. In cases in which these medications later failed, the patients who proceeded to surgery then had larger glands. This fact contaminates the concept that larger glands would lead to more surgical intervention because the common use of these medications induces a selection bias.

KEY POINTS: EPIDEMIOLOGY AND MARKETSHARE

- The incorporation of medical management and new technologies has changed which treatment options are selected for the treatment of LUTS and BPH.
- Laser-based treatments are increasingly used, although multiple factors have affected acceptance.
- Multiple factors in the past decades have changed the type of patient who typically advances to surgical management of BPH. Increasingly these are more challenging clinical scenarios.

WORKUP

The evaluation of LUTS and BPH should always include a detailed medical history with attention paid to assessment of LUTS using a validated questionnaire. A focused physical examination should include a brief neurologic screen, abdominal examination, and genitourinary examination including digital rectal examination (DRE). Urinalysis is another recommended test, and men with a predominant symptom of nocturia should complete a frequency-volume chart (voiding diary). An algorithm for the basic and more detailed workup can be seen in Figures 105-1 and 105-2 (McVary et al, 2011). The specific goals for the patient should be clearly defined from the standpoints of both the patient and the treating physician.

Screening of men for prostate cancer has become a more controversial topic in recent years. The American Urological Association (AUA) BPH guidelines (McVary et al, 2011) recommend the consideration of screening appropriately aged men with LUTS who have a life expectancy of longer than 10 years. The recent guidelines for the detection of prostate cancer recognize that the greatest benefit for prostate-specific antigen (PSA) screening is for men 55 to 69 years of age (Carter et al, 2013). This screening should include DRE and serum PSA if the patient so elects after an informed discussion. Although serum PSA has chiefly been used as a screening tool for prostate cancer, it may also be used as a surrogate for prostate volume, which can be a critical factor in the choice of BPH therapy. For this reason itself, we endorse its use.

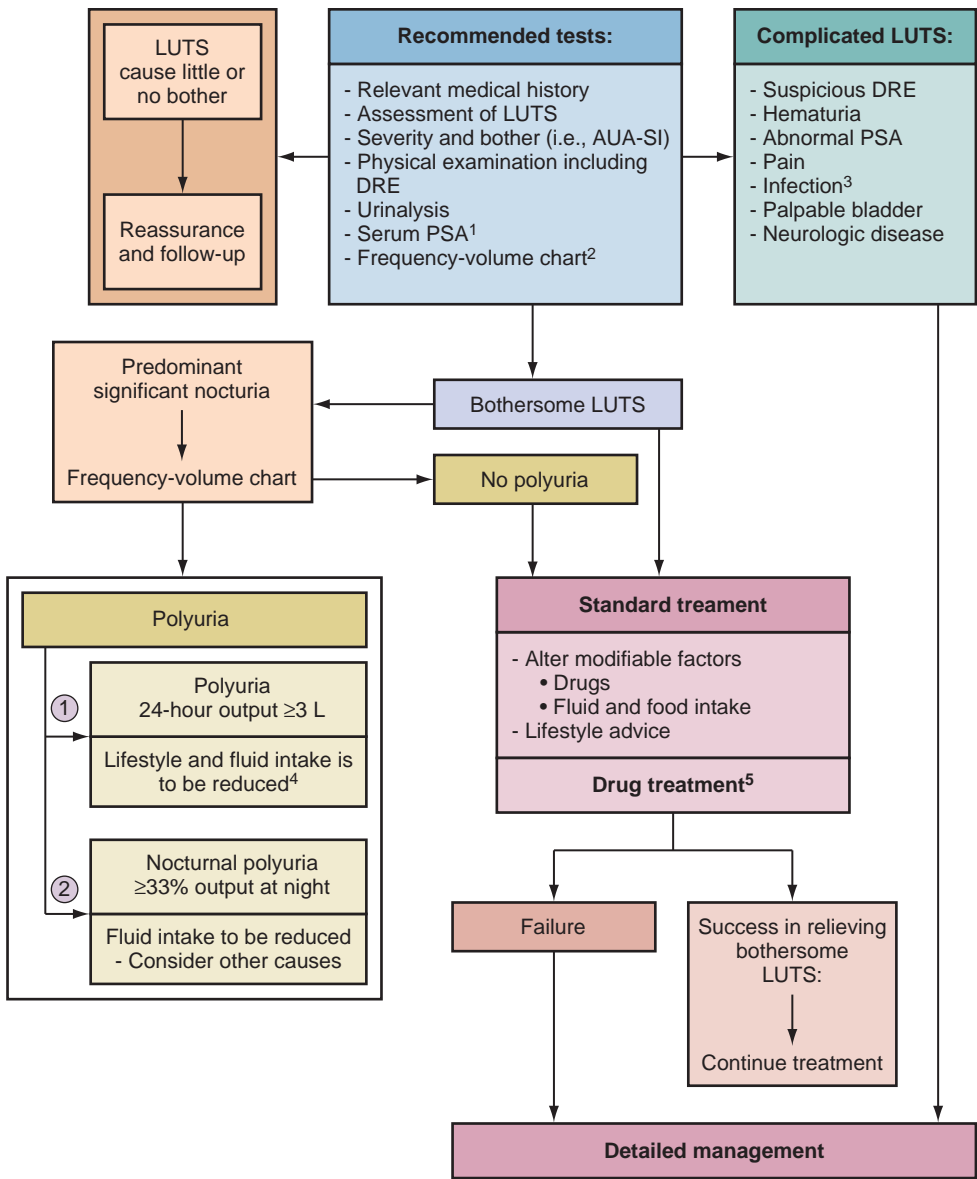

The goals for treatment should be used to guide the clinical evaluation. During the evaluation, the patient's voiding pattern should be assessed along with any general medical problems that may have an effect on the voiding pattern. The role of BPH in the overall voiding pattern should be assessed, particularly with respect to the possible benefits of any treatment. The necessity for treatment along with the probability of success of any treatment should be factored in and weighed against the risk of treatment. Finally, the physician's assessment along with the rationale should be explained to the patient using terms that the patient is able to understand.

DEFINING OUTCOMES

Response Rates

Subjective

Use of validated questionnaire data has become customary in the reporting of symptoms, but other data can be more open to interpretation. How severely a patient defines his dysuria or hematuria after a procedure can affect how they are included in what is often

¹ When life expectancy is >10 years and if the diagnosis of prostate cancer can modify the management. For the *AUA PSA best practice statement: 2009 update*, see: www.auanet.org.
² When significant nocturia is a predominant symptom.
³ Assess and start treatment before referral.
⁴ In practice, advise patients with symptoms to aim for a urine output of about 1 L/24 hr.
⁵ See Figure 105-2.

Figure 105-1. Basic management of lower urinary tract symptoms (LUTS) in men. AUA-SI, American Urological Association Symptom Index score; DRE, digital rectal examination; PSA, prostate-specific antigen. (Modified from McVary KT, Roehrborn CG, Avins AL, et al. Update on AUA guideline on the management of benign prostatic hyperplasia. J Urol 2011;185:1793–803.)

a binary scoring system defining the absolute presence or absence of a symptom.

Objective

Although the most reproducible of results across studies, objective data are also dependent on accurate reporting and thus can be affected by many confounding variables. The most frequent confounders noted are the reporting of changes in patients with long-term follow-up. These data are prone to contamination from multiple sources including patients lost to follow-up and patients who are nonresponders and received additional treatment. Rarely are intent-to-treat analyses reported in series, and in reality the end

points reported typically include those patients who are treatment responders who continued to return for future appointments.

Need for Secondary Procedures

The issues surrounding reporting of secondary procedures have been well delineated in previous versions of the BPH guidelines. In summary, the defined metrics for re-intervention are, in general, rendered by the treating physician. These are difficult to classify because treatment may be triggered by subjective complaints, objective findings, or a combination of the two. **These thresholds can vary by patient or treating physician, and both same-study and cross-study reproducibility and reliability are challenging.** In

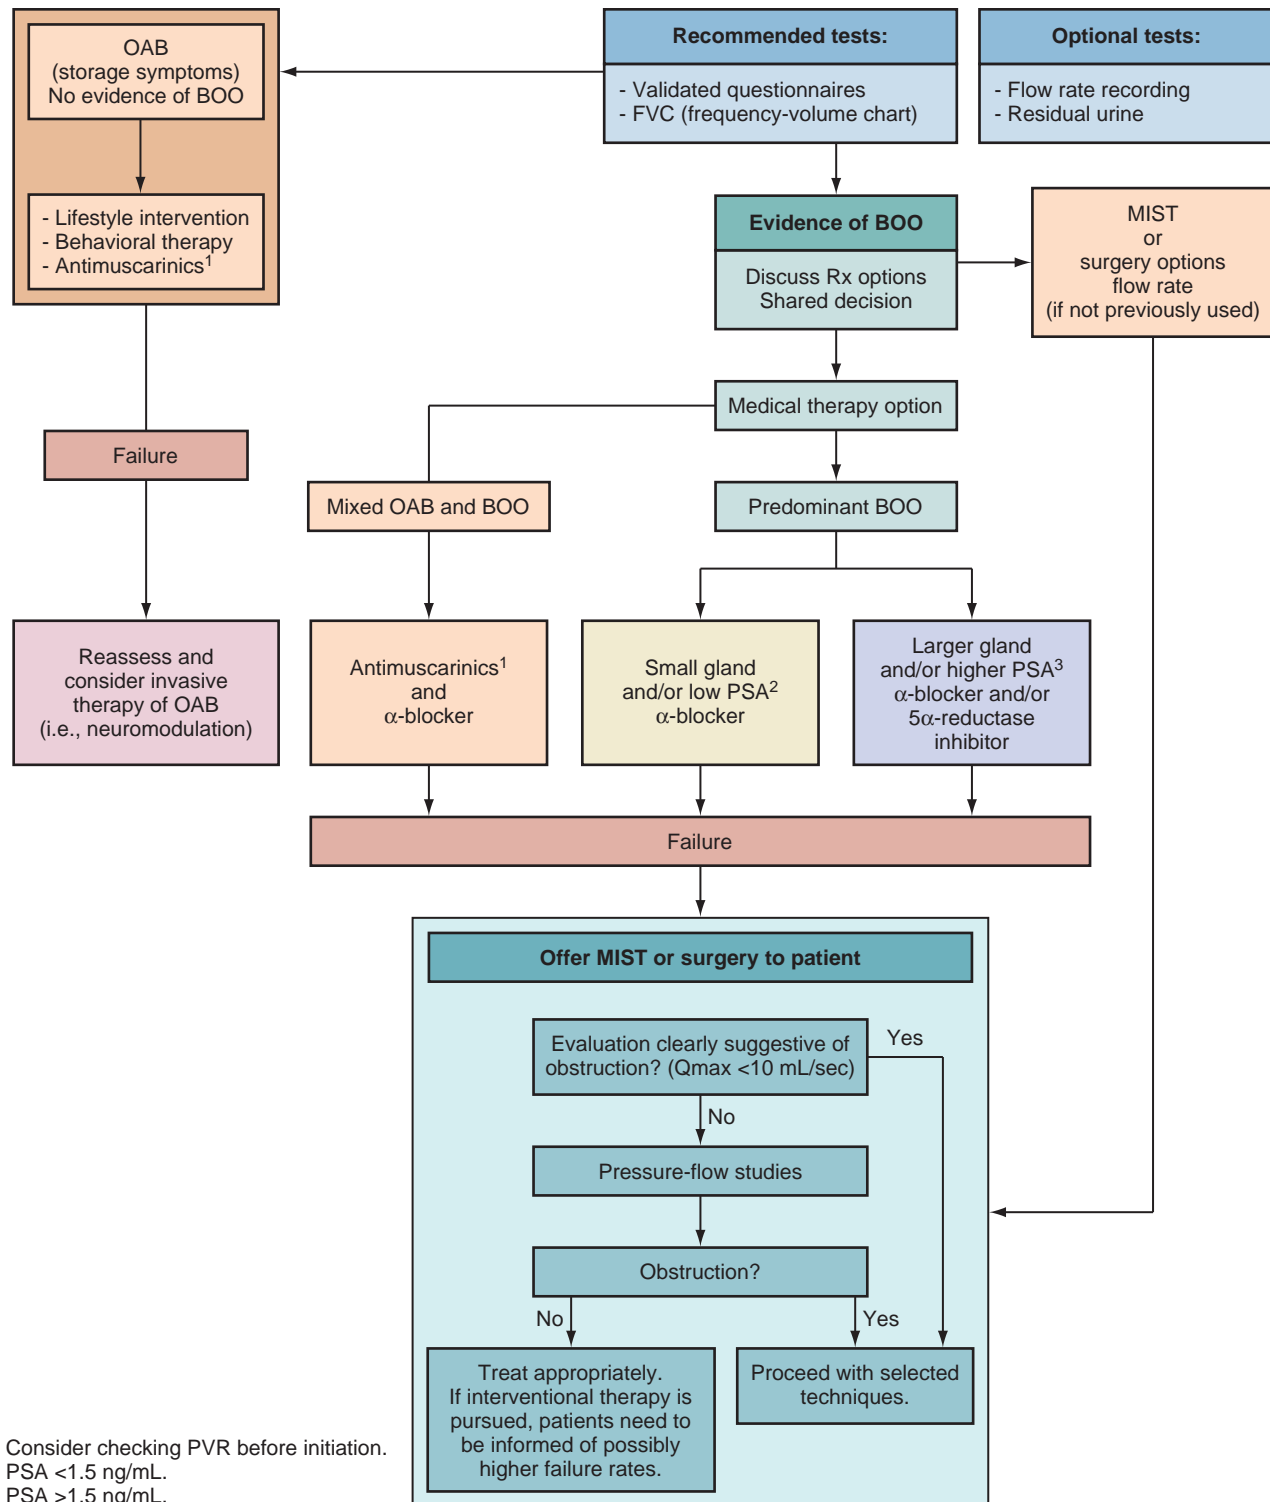

Figure 105-2. Detailed management for persistent, bothersome lower urinary tract symptoms (LUTS) after basic management. BOO, bladder outlet obstruction; MIST, minimally invasive surgical treatment; OAB, overactive bladder; PSA, prostate-specific antigen; PVR, postvoid residual; Rx, treatment. (Modified from McVary KT, Roehrborn CG, Avins AL, et al. Update on AUA guideline on the management of benign prostatic hyperplasia. *J Urol* 2011;185:1793–803.)

addition, patients involved in trials may be more closely followed and carefully scrutinized, causing both the patient and physician to change the threshold (in either direction) at which they may customarily initiate treatment. **Although treatment failures are clearly an important end point because they can lead to an increased overall cost of health care, the current literature can make these issues difficult to interpret clearly.**

Comparisons to Other Treatments

Comparing surgical procedures with one another and with medical management in an equitable way can be challenging. In particular, when comparing studies involving an intervention (which by the nature of the intervention usually does not include a placebo) with those that use a placebo lead-in (common in medication studies),

the former treatment will take full credit for the placebo effect and the true intervention effect, and the latter for only the true intervention effect. Although for the patient these outcomes may feel the same, the comparisons are inherently flawed.

In general, when any new procedure is being accepted into the armamentarium of the urologist, studies begin with a small number of patients from a narrowly defined cohort. If success is seen there, then larger cohorts with broader inclusion criteria follow. Frequently these findings are compared with historical improvements and morbidities seen in early TURP data. These comparisons are somewhat unfair because they compare a current technology with a historical, and often inferior, data set. Studies making broad conclusions based on comparisons with historical controls should be viewed with skepticism.

If a technology truly appears successful, it moves on to the eventual RCT comparing the new technology with another treatment approach. Although the comparative effectiveness trial is a high bar to pass, caution must still be taken when interpreting these results. For instance, the comparison to TURP assumes that the surgeons performing the comparative technique are sufficiently trained and can produce predictable results.

Table 105-1 outlines expected complication rates based on the differing technologies. **Table 105-2** outlines expected outcomes in voiding parameters and is drawn only from RCTs. In constructing tables comparing outcomes and complications, the inequalities of good data with high levels of evidence come to the forefront. Many technologies have meta-analyses of large RCT trials, whereas other included data were dependent on large case series.

This is merely a sign of the available studies conducted. Although any comparison across technologies and time periods may be considered unequal, we attempted to use data from meta-analyses and RCTs, filling in data from large series only when necessary.

PRESURGICAL FACTORS

Indications for Treatment

The most common indication for TURP has shifted considerably in the last few decades. **Although this previously was the presence of voiding symptoms without formal subjective or objective quantification, we now recognize that the indication is more likely to be moderate-to-severe voiding symptoms attributed to BPH that are refractory to medical therapy.** Almost always, both questionnaires and objective data (e.g., uroflow, urodynamics and pressure-flow studies) augment the history and physical examination findings before the decision for surgical management of this condition is made.

AUR can often be indicative of an end-stage bladder. Although the presence of painful urinary retention at a low volume (<500 mL) may be considered a potentially positive sign for a nonatonic bladder, definitive assessment of bladder function can be made definitively only by pressure-flow studies. In a report from [Taube and Gajraj \(1989\)](#), 15 of the 34 men with less than 900 mL drained when the catheter was placed were able to later void without surgical intervention. This was in contrast to only 2 of 29 men who were able to resume normal voiding when more than 900 mL of urine was drained. In a patient with AUR triggered by ingestion of medication such as α -agonists or anticholinergics, it is reasonable to initially place a catheter and allow for the medication to leave the system with subsequent supervised decatheterization. In patients with other situational incidents leading to AUR (postoperative or acute bacterial prostatitis), a similar plan can be used, allowing the exacerbating incident to be treated or allowed to run its course. In the community-based Olmsted County Study ([Jacobsen et al, 1997](#)), 57 of the 2115 men studied developed AUR. Half of these episodes of AUR were related to surgical procedures, and ultimately only 8 of these 57 patients required TURP within 6 months of the incident. The addition of an α -blocker during a spontaneous episode of AUR leading to catheterization is commonly used and has been shown to increase the percentage of patients subsequently passing a voiding trial from 47.9% to 61.9% ($P = .012$) when compared with placebo ([McNeill et al, 2005](#)).

Recurrent and robust gross hematuria is a legitimate indication for treatment of the prostate once other causes (e.g., infection, carcinoma, trauma) have been excluded. This may be done as either a scheduled procedure in the case of a recurrent condition or in the acute setting in a patient with clot retention or continued hemorrhage despite more conservative management options ([Borth and Nickel, 2006](#)). The use of 5 α -reductase inhibitors may also be of benefit in a patient with repeated episodes that are not serious enough to require surgical intervention ([Foley et al, 2000](#)).

The findings of **bladder calculi, bladder diverticula**, and other signs of end-stage bladder decompensation are additional possible indications for surgical intervention, provided medical management has been previously attempted. **Recurrent urinary tract infections** (UTIs) resulting from an elevated postvoid residual (PVR) urine level are also an indication for considering intervention; however, bacterial prostatitis (both acute and chronic) should be excluded as a possible source of these infections. A bladder diverticulum is not an absolute indication for surgery; however, if the diverticulum is associated with recurrent UTI or progressive bladder deterioration, surgical intervention may be warranted. Although bladder calculi are classically an indication for surgical treatment of BPH, the most recent AUA clinical guidelines state that bladder calculi themselves should be treated when diagnosed, and a trial with medical management may be considered once the calculi have been removed.

Bilateral hydronephrosis with renal functional impairment requires relief of the obstruction with the paramount goal of preserving the upper tracts and renal function. With catheterization and relief of obstruction, postoperative diuresis may ensue. If the level of obstruction is confirmed at the bladder outlet, the treating physician should proceed to definitive care only after the patient's general medical condition has been optimized and any sequelae of the obstruction (e.g., impaired renal function, edema) have been fully evaluated or have returned to a baseline status. In the case of bilateral hydronephrosis (or elevated serum creatinine) unrelieved by catheter placement, additional studies should be considered. In patients with long-standing BOO leading to a hypertonic and thickened bladder, the ureters could be obstructed at the level of the bladder and ureteral stenting may be required. Because routine screening for upper tract dilation is not currently recommended in patients with BPH, the urologist should continue to consider its presence in these settings. [Sarmina and Resnick \(1989\)](#) documented previously unrecognized renal failure in 3.7% of the 909 men treated for BPH between 1980 and 1986. They estimated that more than 5% of men with unrelieved BPH-related BOO would have chronic renal insufficiency and concluded that risk would be higher in those with a history of enuresis, UTI, urinary retention, and a history of symptoms for more than 1 year.

An elevated or increasing PVR has been postulated as a possible indication for surgical intervention. However, the urologist should remember that there can be significant variability in this value when assessed over time ([Bruskewitz et al, 1982](#)). The aforementioned "classic" indications for BPH treatment are still relevant, and under these circumstances it is reasonable to forego a trial of medical or conservative therapy and proceed directly to surgical intervention. However, in general, patients should undergo a trial of medical management before proceeding to surgical intervention. Once medical management has failed, patients should be considered for surgical therapy to relieve obstruction and improve LUTS and overall quality of life. Surgery is considered for patients with moderate-to-severe symptoms (AUA symptom score [AUASS] higher than 8) in whom appropriate medical management has failed ([McVary et al, 2011](#)).

Although the validated AUA symptom score is an important questionnaire for the urologist when evaluating a patient with LUTS, it does not completely replace a careful history because it is not diagnostic of LUTS and BPH. The symptom characteristics that the patient reports should carefully be defined through the use of both the AUASS and an interview, and surgery should be used carefully in patients with predominant storage symptoms unless these symptoms are thought to be a result of problems emptying the bladder.

OP was the mainstay of treatment for LUTS from BPH for decades and is still an excellent treatment option. Covered in detail elsewhere in this text, this treatment is useful in men with very large glands, which still may be a challenge for endoscopic treatment, and in men who need treatment for large or multiple concomitant bladder calculi or diverticuli.

Antibiotic Coverage

Antibiotic coverage for surgery should be carefully considered for each patient with reference to the AUA Best Practice statement ([Wolf et al, 2008](#)). The minimum coverage would include either the use of a fluoroquinolone or trimethoprim-sulfamethoxazole (TMP-SMX). However, if the patient has an indwelling catheter (urethral or suprapubic), then extended coverage should be considered.

Sepsis is still an occasional occurrence after TURP, and antibiotics should be carefully selected. A European series ([Vivien et al, 1998](#)) with 857 patients had a bacteremia or septic shock rate of 2.3%. Risk factors for bacteremia or sepsis included preoperative bacteriuria and surgery longer than 70 minutes. The center where the surgery was performed was noted to also be a risk factor, implying that surgeon factors such as antibiotic choice or technique may be a factor.

The practice of extended antimicrobials is supported by the frequency with which patients with indwelling catheters have a positive (and often polymicrobial) urine culture (Warren et al, 1982). The spectrum of these organisms is variable, with factors such as local patient population, facility specifics, and previous antimicrobial treatment all affecting the latent organisms. In addition, patients with long-term catheters are often exposed to antimicrobials, and they may have an increased risk of resistance (Bjork et al, 1984).

Histologic Specimen

In an era before PSA screening, prostate cancer was frequently diagnosed by the examination of the pathologic specimen obtained during TURP. With the increase in many treatment options that do not procure a specimen, there is some concern that we may be missing clinically significant cancers. The advent of common PSA screening was shown to decrease incidentally found cancer from 12.9% to 8.0% in one series (Mai et al, 2000). A series from Tombal and colleagues (1999) looking at a 13-year period around the time of the incorporation of PSA screening found a decrease in all T1 cancers from 23% to 7% of specimens from BPH treatments with a greater effect on T1b disease (decrease from 15% to 2%). Patients with incidentally found prostate cancer during TURP were more likely to have organ-confined disease and lower Gleason scores than men in whom cancer was detected by prostate biopsy (Helfand et al, 2009). The recently published study from Meeks and coworkers (2013) concluded that in men with a PSA under 4 ng/mL, the finding of a clinically significant cancer would occur in only 1 of 382 TURPs, making a total of 390 such cancers detected nationally in a 3-year period. In a pool of 60,000 laser vaporizations, 163 clinically significant cancers would be missed. Taken in concert, these studies indicate that in men who have undergone adequate PSA screening, relatively few clinically significant prostate cancers would be missed by use of a technology that does not obtain a pathologic specimen.

Matching Treatment with Patient

Multiple patient factors may lead the urologist to recommend a particular treatment option for a patient; each treatment has its own inherent risk, benefit, and safety profile. Some patient factors to consider are prostate size, previous surgical intervention, history of urinary retention, inability to stop ongoing anticoagulation, surgeon experience, and, of course, patient preference. Factors more specific to the surgeon would include surgeon experience with different treatments and their availability at that institution. Historically, the urologist used DRE or cystoscopy to estimate prostate size. DRE has been found to overestimate small glands and underestimate large ones, even when performed by an experienced endoscopic savant. During cystoscopy, each centimeter above the normal 2.5-cm prostate length would roughly equate with an additional 10 g of additional prostate weight. Although these may give the treating physician a general idea of prostate size, these types of assessments have been shown to be inaccurate. **If gland size may lead the urologist to choose between two different treatment techniques, the patient may be well served by undergoing office transrectal ultrasonography (TRUS) to precisely assess prostate size before deciding on the surgical intervention.** Most urologists have an algorithm wherein they use prostate volume to dictate their recommendation for surgical intervention, with a very large gland leading the urologist to bipolar transurethral resection of the prostate (B-TURP) or OP and a smaller gland leading toward laser or photoselective vaporization of the prostate (PVP). However, more and more data are being generated showing efficacy of laser methods in larger glands (discussed in the laser TURP section). We prefer the use of laser TURP for glands with a volume less than 100 mL, with B-TURP for glands 100 to 150 mL and OP for glands larger than 150 mL. Regardless of the specific cutoffs used for each technology, it is a wise urologist who adheres to the AUA guideline suggestion that the choice of approach should be based on the patient's individual

characteristics including anatomy, the surgeon's experience, and discussion of the potential benefit and risks of complications (McVary et al, 2011).

Additional factors that may also lead to the use of conventional loop resection over laser treatment include the presence of a median lobe or a ring of intravesical prostate. The use of a loop in this situation may be preferable because it allows a less than well-versed surgeon an option to reach out and "pull" the protruding prostate away from the bladder wall during resection. With increasing age and comorbidity, patients may now frequently be on anticoagulation when the urologist recommends surgical therapy. The inability of these patients to come off of their anticoagulation may lead the urologist to a difficult decision with regard to treatment options. Patients unable to cease anticoagulation for surgery may frequently be counseled that a treatment such as laser TURP may limit their surgical risk because this technique appears to have improvements over TURP in terms of bleeding risk.

KEY POINTS: PRESURGICAL FACTORS

- In general, patients should undergo a trial of medical management before proceeding to surgical intervention. Patients in whom medical management fails may be considered for surgical therapy.
- Perioperative antibiotic coverage should not be neglected because serious adverse outcomes still occur.
- Both patient and physician factors should be considered when selecting the appropriate surgical treatment for patients.

SPECIFIC TECHNOLOGIES

Nonlaser Options

Monopolar Transurethral Resection of the Prostate

TURP involves an endoscopic approach via the patient's urethra to surgically remove the inner portion (primarily the transition zone) of the prostate that encircles the urethra. An electrified wire loop is used to remove the portion of the prostate between the bladder neck and the verumontanum to a depth of the surgical capsule. The current is carried from the cutting loop through the tissue (and patient) to the return electrode in the grounding pad. Although the procedure is still considered the gold standard for BPH treatment, the morbidity associated with it has led to the development of many endoscopic alternatives to the classic M-TURP.

The original M-TURP requires the use of a nonionic irrigant (water, glycine, sorbitol) to allow electroresection of the prostate. The use of an ionic solution (i.e., normal saline) leads to dissipation of the cutting current and poor cutting efficacy. Troublingly, these nonionic solutions are hypo-osmolar and can be problematic when absorbed through open prostate sinuses into the systemic circulation. To combat this, many of the newer treatment options have adapted to accommodate the use of an iso-osmolar solution such as normal saline.

The first transurethral resection was developed in the United States during the early 20th century. The original optical system was a small series of lenses, which was updated to a solid glass rod lens system with fiberoptic lighting by Hopkins (1976). The addition of a video system that does not require the urologist to apply the eye to the lens is another significant adaptation that has improved both visualization and training.

Technique (from Preoperative Area to Recovery Room)

Preoperative. In general, TURP is performed using general or spinal anesthesia. Traditionally, TURP was accomplished with the patient under spinal anesthesia so the anesthesiologist could monitor for signs of transurethral resection (TUR) syndrome resulting from hyponatremia. However, this practice has become less commonplace for this indication, although the method remains useful.

Restall and Faust (1979) highlight many reasons that regional anesthesia is a desirable choice in patients undergoing transurethral prostatic surgery. Excellent skeletal and smooth-muscle relaxation allows easy filling of the bladder and reduces bladder spasms. However, neurologic deficits, potential bleeding tendencies, chronic low back pain, and osseous metastases are potential problems. In addition, the lack of patient acceptance may also limit the use of regional anesthesia (Brunner and Echenhoff, 1977).

Once adequate anesthesia has been initiated, the patient should be positioned and secured in the dorsal lithotomy position and padded appropriately to prevent positioning injury, with special attention paid to the patient's legs. **The patient's buttocks should be placed near the table edge so that the table does not impede the full course of the scope. If not positioned far enough down the table, the anterior portions of the prostate may be difficult to reach,** particularly in patients with fixed pelvic anatomy from previous pelvic injury, orthopedic history, radiation, or trauma. Adequate antibiotic coverage should be given as detailed previously. A quick abdominal examination will provide a baseline for any subsequent intraoperative examination should a perforation occur during the procedure and lead to prevesical irrigant accumulation. Shaving of the genitals and perineum is not required, and any variety of standard skin preparations may be used on the lower abdomen, genitalia, and perineum. If required, a grounding pad should be placed on the leg outside of the surgically prepared area with the grounding pad placed on the contralateral leg to any previous joint replacement surgeries. Use of the O'Connor type rectal shield provides ready, sterile access to the rectum in case the prostate needs to be lifted anteriorly for resection. Irrigating fluid should be maintained at body temperature and placed at the lowest height relative to the patient to provide adequate visualization. **Fluid level may be raised during the procedure if visualization becomes obscured because of bleeding.**

Intraoperative. Before the resectoscope is inserted, it should be assembled to make certain all elements are appropriately fitted and in working order. The use of a video camera mounted to the lens is largely standard at this point because few urologists prefer to place the eye directly to the lens. Some urologists prefer an instrument that permits a continuous flow of irrigating fluid. This can be accomplished either via a passive mechanism into the cystoscopic drape or with the aid of a machine that allows for an active removal of the fluid from the bladder.

The plan for resection can be varied by any number of patient factors, and in general the best approach is the one best practiced and understood by the urologist. Despite the multiplicity of approaches, some generalizations are proposed here with the consideration that the surgeon should always take an organized and systematic approach.

Before the resection is begun, the bladder should be inspected for any bladder pathology (e.g., tumor, diverticuli). The presence of an unsuspected bladder tumor may necessitate a change in plan, with resection of the bladder tumor performed immediately and TURP scheduled for the future after pathologic staging is complete. The bladder neck, trigone, and position of the ureteral orifices, verumontanum, and external sphincter should be noted, and their relationship to the prostatic adenoma confirmed. If the surgeon has difficulty identifying the ureteral orifices, indigo carmine may be given intravenously by the anesthesiologist, with the efflux seen coming from the orifices a few minutes later. The type of irrigant used is based on the type of resection planned, but in general normal saline is used for bipolar resection and glycine or water is used for monopolar resection. In situations in which the cutting element does not seem to be functioning, there is a general algorithm to check: The connection to the scope and generator should be checked, the irrigating fluid should be inspected to verify that it is commensurate with the generator technology being used, and, if a monopolar technology is being used, one should check that the patient is properly grounded. The opening of the procedure should start with resection of any impediment to movement of the irrigating fluid. The presence of a middle lobe should lead the surgeon to start the resection there. The numerical choice of current is also

dependent on the surgeon's preference, but mixed currents typically provide a great hemostasis with less cutting ability. Once a median lobe has been removed, the lateral lobes of the prostate may then be tackled by the resectionist.

When resecting the lateral lobes, some surgeons prefer to resect the floor of the prostatic urethra initially (between the 5 and 7 o'clock position), whereas others use a modification of the Nesbit (1943) "encirclement" approach (Fig. 105-3 on the Expert Consult website). In the Nesbit approach, resection is initiated at the 11 o'clock to 9 o'clock and the 1 o'clock to 3 o'clock positions. The resection exposes but does not resect the bladder neck fibers and carries the resection proximally to the base of the verumontanum, avoiding any injury to the external sphincter (Thompson, 1975; Greene, 1979).

Surgeons starting with the prostatic floor usually start by resecting a "channel" at either the 5 or 7 o'clock position and resecting down to the surgical capsule of the prostate (Fig. 105-4). By finding the surgical capsule early in the procedure, the depth of the resection is set. The channel is then widened (usually laterally) and then carried up the lateral walls toward the anterior aspect of the prostate, following the surgical capsule as the depth of resection. The resectionist may note that the lateral lobes will begin to "fall" into the fossa as they are resected, making subsequent resection easier. Ultimately, the area between the 5 and 7 o'clock positions is then resected at the final stages of the procedure to smooth out the prostatic floor and finish the procedure without undermining the bladder neck during multiple movement of the scope.

In either resection schema, the initial stages of the resection should involve long, smooth tissue cuts. The produced prostate chips should be long and canoe-like in appearance, with a length equivalent to the extended resection loop. A synchronized, rocking motion with the resectoscope allows the resectionist to follow the prostate shape and achieve the desired chip shape and resection. One should avoid cutting chips of insufficient length or thickness because this is inefficient and may lead to an irregular resection bed that hides bleeding areas. As the resection progresses, the surgeon may need more deliberate pressure on the resectoscope to reach more lateral and anterior aspects of the prostate. For surgeons using the O'Connor shield, digital elevation of the prostate may aid in resection. In general, aggressive resection of the anterior and apex of the prostate is postponed until the end of the procedure. The anterior aspect of the prostate fossa has the least depth of adenoma and is easily perforated. In addition, **the sphincter has a slight tilt, with the anterior portion of the sphincter being the most proximal in the urethra.** Although emptying the bladder may allow this anterior portion to become more visible to the surgeon and aid in resection, adequate fluid should be kept in the bladder to avoid inadvertent bladder perforation with the loop extended.

Over-resection (including capsular perforation) in any area before the major portion of the adenoma has been removed may expose large venous sinuses. Exposing these sinuses will predispose to bleeding and fluid extravasation and absorption and compromise the resection and patient outcome. **The prostate apex is best resected at the end of the procedure in a bloodless field where resection can be done precisely to avoid injury to the external sphincter.** A finger placed in the rectum via the O'Connor shield may also aid in the resection at the apex. A limited amount of residual tissue may be left near the verumontanum, because it is certainly preferable to repeat the procedure than to make the patient incontinent with an overzealous resection near the apex.

Hemostasis should be maintained throughout the procedure. Arterial bleeding is characterized by its bright red color and persistence even with irrigation running over the area of hemorrhage. In addition, this type of bleeding will persist during filling and drainage of the bladder. Arterial bleeding should always be controlled, and precise fulguration is paramount. If vision is obscured, the cutting loop may be advanced to place the loop on an area of bleeding, with the fulguration current then used to control the arterial end. "Ricochet" or "bounce" bleeding from the opposite wall or a cryptic bleeding site that requires further, deeper resection should also be kept in mind (Greene and Holcomb, 1979).

Figure 105-3. Approach to transurethral resection of the prostate by starting the resection anteriorly. A to C, First stage of resection of the prostate. The resection is begun at the 12 o'clock position, and the tissue at the bladder neck and the adjacent adenoma are resected in quadrants. D, The midportion of the gland is resected starting at the 12 o'clock position and carrying it down to the 9 o'clock position. E and F, The sagittal and coronal section views are shown.

Continued

Figure 105-3, cont'd G, The resection is now begun at the 12 o'clock position, and the left side of the patient's gland in the midfossa is resected down to the 3 o'clock position. H and I, Sagittal and coronal sections are shown. J, The midportion of the gland is resected farther down from the 9 o'clock position to the 6 o'clock position. K and L, Sagittal views.

Figure 105-3, cont'd M to O, The tissue remaining at the apex is now resected. Resection is initiated next to the verumontanum and carried toward the 12 o'clock position. P to R, Residual tissue is carefully cleared on the patient's right side.

B, Resecting a lateral lobe. C, Sagittal view of resection of prostate floor. D, Continuing resection down to capsule. E, Resection of this section of prostate complete, leaving some residual apical tissue to avoid injury to external sphincter. (Modified from May F, Hartung R. *Surgical atlas: transurethral resection of the prostate*. BJU Int 2006;98:921–34.)

Identifying bleeding at the bladder neck (particularly anteriorly) can be facilitated by nearly emptying the bladder.

Venous bleeding can be more vexing and typically appears darker in color than arterial bleeding. Venous bleeding will often disappear with a full bladder because it applies pressure to the prostatic fossa. Identifying venous sinuses may be difficult owing to the lack of persistent bleeding with rapid irrigation influx, and controlling of the bleeding with fulguration may be even more challenging. Once again, the cutting loop may be used to temporarily tamponade any bleeding with precise fulguration. If the venous bleeding is unable to be completely controlled (as is frequently the

case), a catheter may be inserted and the balloon inflated and pulled to traction for tamponade of venous bleeding.

Before the operation is terminated, all tissue must be removed from the bladder, with careful attention paid to make sure prostatic chips have not fallen into any bladder diverticuli that may exist. An Ellik or Toomey syringe may help facilitate removal of any tissue. The prostatic fossa should be examined again as one of the final steps, with control of any arterial bleeding. A large-bore catheter should be carefully placed into the bladder with the use of a wire catheter guide if required. The amount of fluid placed in the balloon should be tailored to the volume of resected tissue to avoid the

catheter balloon falling into the excavated prostatic fossa. In our practice, the Foley catheter is usually placed to traction for a short time, with release of traction based on residual hematuria. The use of continuous bladder irrigation (CBI) is not compulsory but can be used if the irrigant is not clear at the end of the procedure.

Placement of a three-way catheter at the end of the procedure does not commit the patient to CBI, because the inflow port can always be obstructed with a catheter plug. If CBI is elected, skilled nursing is preferable; an unrecognized obstruction to the outflow tract can lead to bladder distention and a worsening of bleeding. Intermittent irrigation may also be used but requires extra attention to the inflow and outflow patterns.

Postoperative. Most patients undergoing TURP have an uneventful postoperative course (Mebust, 1993). The diet can quickly be advanced in the postoperative period, and the patient may ambulate on the day of surgery if there is a mild degree of hematuria. When ordering postoperative fluids, one should remember that even an uncomplicated resection involves fluid absorption of 800 to 1000 mL (Oester and Madsen, 1969). Patients with persistent complaints of bladder spasms or rectal discomfort should prompt the clinician to examine the catheter to make sure it is not obstructed.

In the absence of significant capsular perforation or persistent bleeding, the catheter can be removed in 24 to 48 hours. If minor bleeding persists beyond this timeframe, the patient may be discharged to home with the catheter in place with close outpatient follow-up. Whereas a wide variety of practice patterns exist, patients may be discharged to home with or without the catheter; we typically discharge patients on postoperative day 1. The use of narcotics for pain control is almost never necessary, and they should be avoided at discharge.

The use of stool softeners in the postoperative period (extending out a month from surgery) is likely beneficial because passage of hard, impacted stool may precipitate bleeding. Patients should avoid activities that place excessive or uneven pressure on the perineum (i.e., horseback riding, use of a riding lawn mower) for 4 to 6 weeks to not incite any postoperative bleeding while the freshly resected prosthetic bed re-epithelializes. Epithelialization of the prostate bed occurs by migration and proliferation of transitional cells for the resected margins. This usually requires a few weeks, and patients frequently report dysuria during this time. The long-term use of phenazopyridine is discouraged but may help patients overcome this dysuria in the immediate postoperative period. Patients should be warned that this medication may make bodily fluids appear red-orange in color and can stain contact lenses. Patients should be warned that they will frequently pass tissue or eschar with some minor delayed bleeding for 1 to 4 weeks from the time of the procedure, to alleviate any anxiety when this occurs. It is our practice to have the patient refrain from any sexual activity because of concern about precipitous bleeding, even though this is clearly a matter of expert opinion.

Patients with long-standing obstruction (particularly those with urgency and frequency preoperatively) will often experience a continuation or exacerbation of these symptoms in the postoperative period. If proper bladder emptying can be verified, an anticholinergic medication during this time may help the patient feel more comfortable. It is our practice to warn men with preoperatively documented detrusor overactivity that patience will be required in the months after surgery to see if this resolves. Such caution goes a long way in encouraging patients to adopt a strong coping mechanism rather than a polypharmacy approach.

Outcomes. Although morbidity data for men after TURP are commonly cited in a negative fashion, these data should not detract from the large number of men who benefit from the procedure. The number of patients who judge their voiding symptoms to be "better" or "much better" depends partly on the initial severity of symptoms and duration of follow-up but is, in general, above 75% and can be as high as 93% (Bruskewitz et al, 1986; Fowler et al, 1988; Lepor and Rigaudo, 1990). The review for the Agency for Health Care Policy and Research (McConnell et al, 1994) indicated an overall symptomatic improvement of 88% for TURP. This data review indicated that, in general, surgical

procedures (OP, TURP, transurethral incision of the prostate [TUIP]) produced about an 80% improvement in symptom scores compared with 30% to 40% for placebo and nonsurgical therapies. The large, multicenter Veterans Administration study was conducted before the common use of medical treatment for BPH and compared TURP and watchful waiting (Wasson et al, 1995). TURP was considerably more effective than watchful waiting in improving symptoms and avoiding treatment failure. More substantial benefit was noted in men with severe urinary symptoms; men who were substantially bothered had a 91% chance of improvement compared with 62% in those who were bothered less significantly.

Considerable and durable changes in AUASS, quality-of-life (QoL) score, maximum flow (Q_{max}), and many other voiding and lifestyle metrics have been observed with TURP. The procedure's symptomatic durability was recently shown by Masumori and colleagues (2010) in their analysis of patients available 12 years after TURP. Although patients started out with an overall fairly low AUASS (16.7), they improved by 75% at 3 months postprocedure. The difference was less pronounced (40% decrease compared with baseline) but still statistically significant at 12 years. QoL scores followed a similar pattern, with a 67% decrease at 3 months compared with baseline, a decrease that was still significant but less pronounced (52%) at 12 years. The patients with confirmed BOO by pressure-flow study performed better than those without this finding. Patients with urodynamic study (UDS) findings of detrusor overactivity or underactivity did not differentiate themselves with regard to change in AUASS compared with the rest of the cohort. In an analysis 7 years after M-TURP, Nielsen and colleagues (1989) found an improvement in maximum urine flow of 106% at 1 year with a 28% improvement at 7 years. Of the 44 patients still able to be evaluated at 7 years, 16% required repeat resection.

In general, recent data on M-TURP need to be drawn from the procedure as the control group in RCTs. Marked reductions in AUASS and QoL score are typically seen with significant improvements in Q_{max} and UDS parameters. An increase in Q_{max} from 125% to 175% and a reduction in AUASS of 75% are frequently seen. In addition, rarely does a competing technology have a lower risk of BPH-specific re-treatment.

In RCTs comparing TURP with other treatments for LUTS and BPH, TURP is usually at least equivalent if not superior in terms of outcomes focusing on improvements in voiding, with most other treatment options having better safety and adverse events profiles.

Transurethral Resection of the Prostate in the Anticoagulated Patient. A controlled study by Dotan and colleagues (2002) looked at patients undergoing bridging with low-molecular-weight heparin and early resumption of warfarin after stopping warfarin 5 days preoperatively. The average change in hemoglobin was not statistically different, and although the study group did more frequently require transfusion, this difference was also not significant (NS).

Chakravarti and coworkers (1998) used a different strategy; patients underwent only a 2-day cessation of warfarin before surgery, with intravenous heparin substitution during cessation. Only 11 patients were studied, and they had a modest decrease in hemoglobin (1.6 g/dL) with surgery. However, three patients were readmitted within 30 days for bleeding issues. In a multicenter study of 612 patients (Descasez et al, 2011), 33% were on blood thinners before surgery (55 on warfarin, 74 on clopidogrel, and 62 on aspirin). All patients discontinued warfarin and clopidogrel for surgery, with most patients being bridged until surgery with some form of heparin. Only 3 patients continued their aspirin through surgery, with the majority of those stopping aspirin also getting a heparin bridge. Follow-up was taken out to 3 months; patients undergoing any form of anticoagulation had higher rates of transfusion (1.9 vs. 1.0, $P = .026$), bladder clots (13 vs. 4.7, $P < .001$), and thromboembolic events (2.4 vs. 0.7, $P = .02$). Follow-up studies have found differing results (Raj et al, 2011; Taylor et al, 2011).

A dose-escalating, randomized, double-blind, placebo-controlled trial on a heparinoid medication showed a dose-dependent increase in blood loss when given during the time of TURP. Bleeding was so

significant at the highest dose that the study was stopped prematurely (ten Cate et al, 1987). Aspirin has also been studied in the perioperative period. A well-designed prospective, randomized, double-blind, placebo-controlled study looked at patients randomized to 150 mg of aspirin or placebo for 10 days before TURP. With no difference in intraoperative blood loss, the aspirin group had a significantly higher postoperative blood loss. There was no statistical difference in transfusion requirements, but more units of blood were used in the group on aspirin (Nielsen et al, 2000). Two older controlled studies concluded there was no difference in blood loss for patients continuing aspirin through surgery (Thurston and Briant, 1993; Ala-Opas and Gronlund, 1996).

In summary, TURP in the anticoagulated patient carries significant risk, and authors have postulated that laser options may be preferable in patients who are unable to come off of anticoagulation for surgery (Descaseaud et al, 2009).

Complications. Despite decades of use, M-TURP still has a considerable intraoperative complication rate. Although the overall complication rate has improved, there is still at least a 3% chance of intraoperative complications (Ahyai et al, 2010), primarily hemorrhage leading to transfusion. However, with other MISTs requiring more frequent reoperation, the perioperative and late complication rates of M-TURP continue to make it a viable option in the correctly chosen patient. The overall morbidity of TURP continues to approach 20% when studies include blood loss requiring transfusion, infections, strictures, sexual dysfunction, urinary incontinence, urinary retention, and the development of TUR syndrome (Mebust et al, 1989; Borboroglu et al, 1999).

Intraoperative and Perioperative. There is always the possibility of absorption of the irrigating fluid into the patient's systemic circulation during resection of prostatic tissue and TUR syndrome does still occur. Much of our current understanding of the cause of TUR syndrome starts with work from the 1950s (Hagstrom, 1955; Harrison et al, 1956). The prostatic venous system has a pressure of approximately 10 mm Hg, and fluid at a pressure exceeding this will lead to fluid absorption when these vessels are exposed during resection. The absorption of the hypo-osmolar irrigating fluid leads to an acute dilutional hyponatremia with resulting neurologic changes (confusion, nausea, vomiting, visual changes, hypertension, tachypnea, and bradycardia). Now with the use of isotonic, iso-osmolar irrigating solution and the bipolar electroresection system, this risk has theoretically been eliminated. TUR syndrome was seen in 2% of patients in the AUA cooperative study (Mebust et al, 1989). Larger glands (>45 g) and longer resections (>90 minutes) were risk factors. The recent meta-analysis of RCTs found a lower incidence, with only 0.8% of patients developing TUR syndrome (Ahyai et al, 2010). Most authors agree that TUR syndrome is caused by dilutional hyponatremia, but there have been alternate causes proposed. Hoekstra and colleagues (1983) and Ryder and colleagues (1984) noted elevated serum ammonia levels after glycine irrigant resections. Excessive glycine absorption led to liberation of ammonia from metabolic pathways, leading to immediate or delayed encephalopathic symptoms.

Several steps can be taken to prevent this complication. Use of a bipolar resection method should certainly be considered. The height of the irrigating fluid above the patient should be carefully chosen. Madsen and Naber (1973) demonstrated that the ideal height of the fluid was 60 cm above the patient. From their work, this appears to be the minimal height to maintain good vision but also not lead to excessive systemic fluid absorption. Increasing the height 10 cm above this leads to increased pressure in the prostatic fossa and a greater than twofold increase in systemic fluid absorption. Diagnosis of this condition is made by assessment of neurologic status and comparison with laboratory values. Serum sodium should be obtained in long, large resections postoperatively (or intraoperatively if concern exists). A serum sodium level of less than 120 mEq/L indicates a significant dilution and may lead to coma or seizures. Transient visual disturbances or blindness indicate central nervous system toxicity and are obviously very distressing to all the parties involved.

If profound central nervous symptoms are noted, judicious administration of hypertonic saline should be instituted. Formulas exist to help guide this resuscitation; overly rapid correction of hyponatremia may lead to a demyelinating lesion of the brain (central pontine myelinolysis).

In either resection approach, the scope may need to make multiple trips across the prostatovesical junction, leading to trigone undermining. If during initial resection the dorsal aspect of this junction becomes overly resected, these trips may become more challenging as the scope is forced to move "uphill" and increase the detachment of the trigone from the posterior prostate base.

Ureteral injury is an uncommon complication. Identification of the ureteral orifices should be attempted before resecting. The 70-degree lens and intravenous injection of an agent that colors the urine (methylene blue, indigo carmine) may be of aid to identifying the ureteral orifices. If the resectionist is still unable to identify them because of a high bladder neck or large median lobe, resection should begin in the midline, taking down the median lobe as described earlier. After this is accomplished, the ureteral orifices may become more apparent to the resectionist without the mass effect of the median lobe obscuring the view.

Hemorrhage in the resected area is a common complication both during and after TURP. Every effort should be made to achieve hemostasis during the operation to prevent the need for a return to the operating room. The risk of transfusion in patients undergoing TURP is low, but transfusion still occurs and patients should be counseled appropriately. Ideally, hemorrhaging areas are controlled as the procedure is ongoing. In general, arterial bleeding should be fulgurated during the procedure, although the resectionist may continue to resect arterial bleeding until the capsule is exposed and fulgurate a bleeding vessel at this level. This practice should be engaged in carefully, but is reasonable. Venous bleeding is classically more difficult to control. Fulguration of open venous sinuses should be attempted, but this may be ineffective even in the most trained hands. In these cases, balloon tamponade may be most effective. Once arterial bleeding has been controlled, a large balloon (30 mL) Foley may be placed with 50 to 60 mL of water in the balloon. The catheter may then be put to traction for a short time to see if this relieves bleeding. In certain cases, it may be prudent to continue traction overnight. The Veterans Administration cooperative study of 3885 patients found a transfusion rate of 2.5% (Mebust et al, 1989). Other early data reported high transfusion rates, with over 20% of patients receiving transfusion (Doll et al, 1992). More recent data from an analysis of RCTs found that 4.4% of patients would require transfusion (Mayer et al, 2012).

Perforation may occur at many places during the resection—the prostatovesical junction, the prostatic capsule, and the bladder itself are all possibilities. The electroresection itself or overdistention of a thinned area of the prostatic capsule may lead to frank perforation, with visual evidence often being subtle. The glistening fat of the periprostatic or perivesical spaces is usually a telltale sign of perforation. In unclear cases, cystography (with drainage films) may be used to assess the degree of perforation and the drainage pattern. **Extravasation related to prostatic resection is almost always extraperitoneal.** If bladder perforation occurs near the dome, then cystography should be considered to rule out an intraperitoneal rupture, which would require open closure. Extraperitoneal rupture caused by resection with limited extravasation can almost always be managed with extended catheter drainage and careful observation. In cases of extraperitoneal rupture occurring with extensive extravasation, percutaneous or open drainage may be required.

Persistent penile erection may develop at any point during the procedure and may drastically limit endoscopic movement. Detumescence may occur spontaneously without active management. When this does not occur, detumescence may be encouraged with pharmacologic agents such as phenylephrine (Lue et al, 1986). The anesthesiologist should be alerted to injection of this vasoactive substance because overly judicious use may lead to systemic cardiovascular changes. Considerable attempts should be made with

vasoactive substances, but if these all fail, perineal urethrostomy can be used to gain access in a dire situation.

Postoperative. Original estimates of the incidence of **bladder neck contracture** were 2% (Greene and Holcomb, 1979). Subsequent data have shown this to be a fairly consistent 2%, although a large range (2% to 21%) was found by Ahyai and colleagues (2010). This complication is thought to result from over-resection of the tissue at the bladder neck paired with injudicious fulguration of this area. Undermining of the trigone may create a flap that then heals as a membrane. Patients with this complication customarily report excellent flow rates in the immediate postoperative period, which slowly decrease in the coming weeks, months, or years. This course will be well exaggerated over the usual progression of BPH-type symptoms of a weakening stream. The average interval of development is approximately 6 months from the time of the surgery, but has ranged from 3 weeks to 10 years (Greene and Holcomb, 1979). If serial flow rates are available during this time, the results will predictably get worse as the contracture develops. **Prompt office cystoscopy should be performed to verify the diagnosis.** Gentle dilation in the office with sounds or a dilating balloon may be attempted. If dilation does not prevail, then evaluation in the operating room may be required with endoscopic incision. If the bladder opening appears completely obliterated, intravenous administration of methylene blue and use of suprapubic pressure may help to identify a jet of blue urine to lead the urologist toward the opening (usually located anteriorly). An open-ended ureteral catheter may be placed into the narrowed opening and guide incision of the constricted ring. Incision may be made with a Collins knife or optical urethrotome until the ring springs open. In general, incisions are made aggressively in the patient with a bladder neck contracture after TURP because the sphincter is still anatomically far away; this is in contrast to anastomotic contractures after radical prostatectomy, which sit very close to the sphincter. Once the band has been opened wide enough to accept the cystoscope, additional resection should be avoided because it may exacerbate the healing reaction and cause restenosis. Intractable bladder neck contractures may require an open VY-plasty to solve the problem.

The incidence of **urethral stricture** after TURP has a large variation in reported incidence. The weighted mean in Mayer and colleagues (2012) revealed that this occurs in 4.1% of cases in the 34 analyzed RCTs, although the severity and necessary treatments were not outlined. The cause of urethral stricture is thought to be resectoscope trauma, catheter use, or bacterial infection in the postoperative period. The surgeon should be careful to select an appropriately sized resectoscope sheath to prevent any unneeded trauma. Interesting data from Emmett and colleagues (1957) showed that only 62% of men who underwent urethral calibration had a urethral meatus and fossa navicularis of 28 Fr or greater. **Calibration and gentle dilation of the meatus along with careful visual inspection of the urethra on insertion of the cystoscope may help in preventing trauma that may lead to stricture.** The resectoscope should always be well lubricated. The role of a urethral catheter leading to stricture formation is supported by a comparison of patients with suprapubic versus urethral catheters, wherein the former had a lower incidence of stricture formation (Hammarsten and Lindqvist, 1992).

The internal sphincter predominates as a continence mechanism in men. During the course of a normal resection, this sphincteric mechanism is resected or rendered incompetent (Rolnick and Arnhem, 1949). Without exception, the surgeon must **preserve the external sphincter mechanism** or the patient will have total or stress urinary incontinence. This injury may be caused by errant resection or excessive fulguration around the striated muscle fibers. The verumontanum is an invaluable landmark and should be preserved not only as a landmark during the ongoing resection, but also for any future identification during cystourethroscopy. Resections that are terminated proximal or adjacent to the verumontanum are unlikely to result in significant injury to the external sphincter. However, the extent of the complex smooth and striated muscle fibers making up the external sphincter is not always clearly demarcated. The anterior portion of these muscular fibers is the least substantial, and the sphincter lies on a tilt with the dorsal

portion being the most proximal and therefore most likely to extend into the resection. The poor understanding of the complexities of the external sphincter is most evident when one considers the extent of incision during an external sphincterotomy. This purposeful act often requires considerable depth and length and highlights our poor understanding of post-TURP incontinence. Nonetheless, caution in over-resection of the distal portions of the prostate should be exercised. Even in contemporary studies this is a continued problem. The study by Ahyai and colleagues (2010) found a 0.6% incidence of stress urinary incontinence, and some studies have reported up to 5%. However, this is often a transient issue and rarely requires additional intervention.

Significant hemorrhage in the immediate postoperative period is most often the result of incompletely controlled hemostasis during surgery. Minor hemorrhage requiring minimal irrigation is fairly common, with a wide variability in occurrence among practitioners (Mayer et al, 2012). **Some delayed postoperative bleeding is frequently noted around 1 to 4 weeks postoperatively and is frequently accompanied by some sloughed tissue or eschar.** Outside of this period, the likelihood of bleeding decreases as the time after surgery lengthens. Limited bleeding may occur for many weeks after the initial resection, but it is usually limited and transient in nature. This customarily responds to curtailing physical activity and increasing fluid intake.

Postoperative urinary retention after any BOO procedure is a common finding. Variability is different based on surgical technique and procedure type. In general, prolonged catheterization is used due to persistent bleeding or surgeon preference. In major case series, the incidence ranges from 6.5% to 7.1% of cases and does not appear to have changed over time (Mayer et al, 2012).

The need for re-treatment may arise for many reasons. **Incomplete resection (likely at the apex or anteriorly), poor patient selection, diagnostic error, and intraoperative technical errors are all possible causes.** The need for re-treatment may be related to urethral stricture, bladder neck contracture, regrowth of BPH, or residual BPH left at the previous surgery. In the meta-analysis of RCTs, Ahyai and colleagues (2010) found a rate of 0.5% re-intervention for BPH-type symptoms, with another 0.1% requiring secondary treatment for other causes (e.g., bladder neck contracture, urethral stricture). The need for surgical revision does appear to increase with increasing gland size, with preoperative retention also being a risk factor (Reich et al, 2008).

Urinary storage symptoms are a common finding after any BOO procedure wherein the urethral epithelium is disrupted. The raw prostatic fossa takes time to re-epithelialize, and the patient will likely frequently experience symptoms of **urgency or dysuria** during this time. Although wide ranges have been reported for both urgency (0% to 38%) and dysuria (0% to 22%), the physician can expect an average of 2.2% and 0.8%, respectively (Ahyai et al, 2010).

Ejaculatory problems are a significant concern because the bladder neck is resected as part of the procedure. In the TURP arm of randomized series compared with holmium enucleation, the TURP groups had new incidences of retrograde ejaculation of 62% and 78% (Briganti et al, 2006; Wilson et al, 2006). Multiple large series have reported on the effects of TURP with regard to a **change in erection quality**. In a trial of 644 men, 30% noted an improvement in erections after procedure, whereas only 20% noted worsening function. The percentage of men engaging in sexual activity before and after surgery was essentially identical (Muntener et al, 2007). Another series showed that a capsular perforation during surgery had a relative risk (RR) of 1.12 in postoperative erectile dysfunction (ED) (Poulakis et al, 2006), whereas other studies have not found an increase in risk (Jaidane et al, 2010). **In a comparative study of patients undergoing either TURP or transurethral resection of bladder tumor (TURBT), the baseline voiding and erectile function in the TURBT group was statistically far superior.** However, after prostate resection, the TURP group displayed significant improvements in almost all International Index of Erectile Function (IIEF-15) subdomains, with an impressive improvement in erectile function (improving from 7.18 to 20.74).

After TURP, the groups were no longer statistically different with regard to voiding and sexual function (Jaidane et al, 2010).

Conclusion. Although most men improved in overall quality of life and the important symptom and urodynamic outcomes with M-TURP, the morbidity and adverse events are such that multiple different and, in general, less invasive treatment options have been developed. Many of these technologies do not achieve the same efficacy as TURP, but they are associated with less risk or fulfill a particular treatment niche.

Bipolar Transurethral Resection of the Prostate

Concept. Bipolar resection uses a specialized resecting loop that incorporates both the active and the return portions of the circuit on the same electrode. Consequently, the current does not need to run through the patient to a return electrode (in the form of a grounding pad), and current is kept at the site of the resection. This innovation in design has also allowed for the resection to take place in ionic irrigating solution and has eliminated most of the risk of TUR syndrome.

True bipolar systems meet the criteria set by the International Electrosurgical Commission, which requires both active and return poles to be attached in a single system. Frequently a dual loop design is used wherein both loops are in close proximity to each other at the end of the cutting electrode. In this design, the electrical energy is able to connect between the loops and supply the resecting energy there. Another form of bipolar technology is the Gyrus PlasmaKinetic (PK) Tissue Management System (Olympus Surgical Technologies America, Maple Grove, MN), wherein energy is initially transmitted from the loop into the surrounding saline. This is a commonly used B-TURP technology in the United States, and the mechanism is described in detail here. The saline is vaporized into gas around the loop, with additional energy from the loop then converting the gas to plasma. The excited sodium ions of the plasma give this technology the characteristic orange glow. Once created, the plasma molecules are able to be excited for use in resection. This seems like a dynamic and explosive process, but it actually allows tissue resection at lower temperatures with a lower voltage. In practice, this allows for a more simultaneous cutting of tissue with sealing of vessels, leading to the overall improved hemostasis recognized in studies.

Although the PK loop and scope look almost identical to the conventional monopolar systems, the loop is made of platinum-iridium instead of the standard tungsten. This specialized loop is able to withstand the electrical and thermal stresses that come with the plasma use (Issa, 2008). When the coagulation setting in this system is used, a different process takes place. Plasma is not created, and the input energy from the generator is used to increase the tissue temperature and seals the vessels in the prostate. The depth of energy transmission is not as important as previously seen with the monopolar system. In addition, the lower voltage and temperature used in a plasma system minimize tissue charring and may lead to a decrease in unnecessary tissue coagulation and a subsequent decrease in storage symptoms.

Technique. B-TURP and M-TURP have an almost identical technique with regard to approach to the resection. However, the resectionist may note that the bipolar technology allows for quicker resections; bleeding vessels are less likely to be encountered because the simultaneous cutting and sealing of vessels decrease time spent controlling hemorrhagic areas. The previous generator with the PK system would often have trouble overcoming the additional energy needed to ignite the plasma. The newer SuperPulse generator has increased capacity and has made this less of an issue. However, the resectionist may still note a drag on the loop as it first comes in contact with the tissue.

Outcomes

Single-Cohort Studies. With the B-TURP similarity to its monopolar predecessor, comparative trials quickly arose. Compared with other treatment systems, relatively few single-cohort studies of B-TURP are available in the literature. One of the large early studies reported excellent results with the PK system (Falsaperla et al,

2007). With a relatively short mean catheterization time of 1.3 days, the authors found a mean increase in Qmax of 190% at 12 months after the procedure. AUASS decreased by an average of 79%. Complications were relatively infrequent, with AUR, urethral strictures, bladder neck contracture, and urinary incontinence recorded in only 1.57%, 2.57%, 1.28%, and 0.77% of patients, respectively. A smaller study published around the same time had equally impressive results and included a high percentage (49%) of patients with urinary retention (Ho et al, 2006). Patients had improvements in mean Qmax (6.5 to 18.3 mL/sec) and AUASS (22.6 to 6.5) at 1 year. Plateaus in these improvements were noted at around 3 months.

Comparative Studies. In the excellent review of the bipolar technology by Issa (2008), a 10-year Medline review of outcomes of both M- and B-TURP was conducted for the years 1997 to 2007. He found a similar efficacy with regard to AUASS, QoL score, peak urinary flow rate, and residual urine. Multiple comparisons of the bipolar and monopolar technology have been published by a European consortium (Mamoulakis et al, 2012). Using the Autocon II 400 ESU system (Karl Storz, Tuttlingen, Germany) (Fig. 105-5 on the Expert Consult website), they were able to conduct an RCT comparing monopolar versus bipolar techniques. This generator has a touchscreen system that allows for selection of either a monopolar or bipolar current. Although the study states it is double-blind, the researchers reported that surgeons could not be blinded at procedure and only the assessors were blinded to treatment selected. In addition, resection technique, power settings, irrigant, and anesthesia type were not standardized across treatment centers. Improvements were pronounced in both groups with no difference in voiding outcomes at 6 weeks. The only significant difference over the short follow-up in this study was the decrease in serum sodium, although there was no statistical difference in occurrence of TUR syndrome, mostly because of the low incidence of the event overall. Widespread application of these findings may be difficult because this is a rarely used platform and this is the only RCT using this technology.

Regarding the more commonly studied PK technology, Patankar and colleagues (2006) reported on a 3-week follow-up. Robust changes in AUASS and Qmax were noted in both groups with no statistical difference. Differences in blood loss and time with catheter favored the bipolar group, with postoperative complications such as hematuria, clot retention, and blood transfusion appearing to be more common in M-TURP patients.

A meta-analysis of RCTs found similar results with no difference in AUASS, QoL score, Qmax, or change in PVR (Ahyai et al, 2010), whereas another meta-analysis of RCTs looking at flow rates at 12 months found a slight (0.72 mL/sec) weighted mean increase in the flow rates for B-TURP (Mamoulakis et al, 2009). This finding is not clinically significant and was mostly bolstered by the large difference in a highly weighted study.

A recent large meta-analysis and systematic review was published by Omar and colleagues (2014). They examined 949 abstracts and found 24 trials acceptable for inclusion in the review. No statistically significant differences were found in terms of AUASS or QoL score between groups. The analysis of Qmax revealed improvements that were more significant in the bipolar group at 3, 6, and 12 months but were once again skewed by a few largely weighted studies. The meta-analysis could not show homogeneity between studies and the result was not clinically significant. A second meta-analysis evaluating outcomes only at 12 months found that bipolar devices demonstrated no significant difference in AUASS or prostate volume reductions compared with M-TURP. However, B-TURP seemed associated with a better maximum flow and a lower PVR (Cornu et al, 2014).

Complications. Issa (2008) also reviewed complications from the years 1997 to 2007. The overall rate of adverse events was lower with B-TURP (15.5% vs. 28.6%, $P < .001$) compared with M-TURP. This was mostly fueled by lower rates of bleeding, transfusion, time with catheter, CBI need, hyponatremia, and TUR syndrome differences. Although the overall rate of complications was statistically significant, these individual subgroups consistently favored B-TURP, with only occasional statistical significance.

Intraoperative and Perioperative. Although the most exciting innovation with the bipolar technology is the **ability to perform the resection in an ionic iso-osmolar solution**, other possible improvements in outcomes may be related to this advancement in technology. A well-recognized complication of M-TURP is the bleeding risk, which may lead to repeat irrigations and prolonged catheterization. The energy profile of the bipolar system has a cut-and-seal effect on vessels that should improve hemostasis and lead to decreased bleeding complications and transfusion rates (Issa, 2008).

In the meta-analysis of patients undergoing B-TURP, no patient developed TUR syndrome. Mamoulakis and colleagues (2009) concluded that by treating 50 patients with B-TURP, one case of TUR syndrome could be prevented. The hemostasis achieved during bipolar resection has allowed for reductions in many bleeding measures. An RR of 0.53 for blood transfusion and 0.48 for clot retention were found with bipolar resection when compared to monopolar resection, with 2.3% and 2.7% of patients having these complications, respectively, in the bipolar group (Omar et al, 2014). The improved hemostasis and absent risk of TUR syndrome allows the urologist a longer resection time and the ability to treat larger glands. Improved visualization may also lead to a decrease in capsular perforations and operating time (Erturhan et al, 2007). A decrease in overall immediate reoperation rate (odds ratio [OR], 0.43) was also found in another meta-analysis. (Cornu et al, 2014).

Postoperative. There are many different types of bipolar systems, all using different mechanisms. The TURis systems (Olympus) were originally mistakenly labeled as bipolar systems (Issa, 2008). In reality, the return electrode in these systems was the outer resectoscope sheath. This could potentially expose the patient's entire urethra and penis to the return energy. Ho and colleagues (2006) reported a 6.3% **urethral stricture** rate during procedures in which the TURis system was used. The review of Issa (2008) found an overall risk of urethral stricture of 4.7%, which was higher than in the TURP group (2.7%, $P = \text{NS}$). However, other authors have not found this difference. (Michielsen and Coomans, 2010). The meta-analysis from Cornu and coworkers (2014) found that there was no difference between M-TURP and B-TURP for the incidence of urethral stricture or stress urinary incontinence.

Other late complications such as **bladder neck contracture** and need for **re-treatment of BPH** do not appear to be much different from those found with conventional M-TURP (Ahyai et al, 2010). Overall reoperation rates at 1 year were low in both M-TURP and B-TURP groups and were not statistically different (Cornu et al, 2014). Once again, the improved hemostatic properties of the bipolar technology were evident in the postoperative care; patients are more likely to have reduced **catheter and hospital times** (Singh et al, 2005; de Sio et al, 2006).

Conclusion. Results for the bipolar resection system are encouraging, and this technology will likely replace M-TURP as the gold standard for treatment of BPH in the coming years. Although clinical outcomes are roughly equivalent, the improved hemostasis of the procedure and use of isotonic irrigating solution allow for longer and safer resections. Different systems use different approaches to meet the bipolar standards, but finding differences among systems with regard to outcomes is challenging at this point.

Transurethral Vaporization of the Prostate

See the Expert Consult website for details.

Transurethral Microwave Therapy

Overview and Concept. The objective of transurethral microwave therapy (TUMT) is to locally thermoablate prostate tissue while maintaining normal temperatures in the surrounding nontargeted tissue. This concept uses a specialized urethral catheter with an antenna that generates radially emitted electromagnetic (EM) waves. These EM waves are in the frequency of 915 to 1296 MHz and penetrate tissue to induce changes that produce localized heat. Treatments that achieve temperatures below 44°C

are designated "hyperthermia," those achieving temperatures above 44.5°C as "thermotherapy," and those achieving temperatures above 65°C as "thermoablative" (Perlmutter et al, 1993).

Prostate parenchyma destruction occurs once a crucial **thermal dose** has been reached. This occurs as part of the multiplicative product of the temperature and exposure duration. Therefore, the critical values are the temperature achieved in the gland (not necessarily the same as the temperature generated by the machine) and the period over which that temperature is able to be maintained. **Optimally, the thermal dose should be confined to the prostate gland with minimal to no heating of the nontargeted surrounding tissues such as the external urethral sphincter, bladder neck, and rectum.** Collateral damage to these tissues will induce complications and may limit the treatment effect by inducing automatic shutdowns in the machine. In addition, this misplaced heat may cause significant patient discomfort and inability to tolerate the procedure in the office setting.

The potential advantages of the microwave technology include the convenience of an in-office procedure with rapid patient convalescence and minimal anesthesia requirements. It is the least operator dependent of the treatments for BPH and has an easy learning curve. Patient selection is crucial to achieving results; there are particular factors that need to be examined when considering TUMT. Patient factors such as prostate volume, gland configuration, and the patient's ability to undergo a transurethral treatment under local anesthesia must all be carefully considered. Prostates with marked middle lobe configurations may distort catheter positioning because the middle lobe will go largely untreated and project the microwave in unintended and unsafe locations. Prostate volumes at the extremes (<25 or >100 g) may impede uniform heating and lead to suboptimal results. Those smaller prostates may lead to unsafe heating of extraprostatic locations, inducing complications such as sphincter injury. It is important that patients with pacemakers, defibrillators, and pelvic or penile prosthesis be excluded from treatment because these devices may undergo significant electrical or mechanical damage from TUMT systems. Patients who have undergone previous invasive BPH treatments may have unexpected transmission of the microwaves with dire results.

Significant differences exist among microwave treatment system designs. These include differences affecting antenna design, the heating pattern generated, and the treatment protocol; such differences should be carefully considered when choosing microwave treatment for patients. The original design was considerably investigated but later advanced to a high energy (HE-TUMT) platform that inventors hoped would enhance treatment effect. It appears that the antenna design dictates the heating pattern more than the frequency of wave energy used (Bolmsjö et al, 1996). Currently, the primarily used systems available are the CoreTherm (ProstaLund, Lund, Sweden), Prolieve (Boston Scientific, Boston, MA), Prostatron (Urologix, Minneapolis, MN), TherMatrx (American Medical Systems, Minnetonka, MN), and Cooled ThermoTherapy (Urologix, Minneapolis, MN) (Fig. 105-10).

The various TUMT platforms generate intraprostatic temperatures of 45° to 70°C. The early systems supplied heat ranges from 42° to 44°C and had rather disappointing results. As devices became more advanced, the intraprostatic treatment temperatures increased. The HE-TUMT nomenclature is applied to the more advanced devices at the higher end of this thermal range. Much of the advancement to using higher temperatures was precipitated by the ability of catheter cooling to reduce urethral temperatures during use and reduce intraprocedural patient discomfort.

In these protocols, the energy was slowly increased to allow the patient to gradually adjust to the rising temperature. When heat is applied to the prostatic parenchyma, there is a natural response with vasodilation of local vessels to physiologically dissipate the heat. While making the procedure more tolerable, this slow increase of energy increased procedure times and decreased efficacy. Heat-shock or high-intensity TUMT has been used to decrease this compensatory vasodilation. In this variation, the heat is delivered quickly so that the prostate vessels undergo thrombosis, resulting in improved heat entrapment in the prostate and decreased

Overview and Concept. Prostate vaporization was first performed in 1995 (Kaplan and Te, 1995) and is contemporary with many of the other MISTs. However, this technique used the same set of equipment as TURP at that time with the exchange of the resecting loop for an element with a larger surface area. Strategically, these modifications allowed for a large surface area over which the current could be delivered to the tissue and did not involve tissue resection. These changes allowed for the use of a higher energy that led to controlled tissue vaporization with simultaneous underlying tissue coagulation. This provided the urologist with an improved visual field in which to work and did not require the capital involved with the purchase of new equipment seen with other TURP alternatives at this time.

The power distribution along the electrode provides the advantages of transurethral vaporization of the prostate (TUVP). As the leading edge of the electrode makes first contact with the virgin tissue (low electrical resistance), a high volume of energy is delivered and leads to tissue vaporization. The lagging edge of the electrode interacts with tissue that has already been desiccated to some degree and has a higher resistance. The interaction with the higher tissue resistance at lagging edge leads to additional tissue desiccation along with vessel coagulation. Overall, this leads to a combination of tissue vaporization at the leading edge, with the lagging portion of the electrode then providing almost instantaneous tissue coagulation. This was verified by a two-stage in vivo study with small numbers. Tissue was first treated with either cutting or coagulating current, with a specimen taken by TURP. Examination of the specimen verified that when the cutting current is used, tissue destruction occurs in the form of vaporization with minimal coagulative necrosis. The converse is also true: Coagulative necrosis predominates when coagulating current is used (Juma, 1996).

A variety of different electrodes were used initially, including the VaporTrod (Fig. 105-6; formerly ACMI, now produced by Olympus)—a grooved roller electrode, the most studied of the monopolar options. Additional options included fluted and spiked varieties (Figs. 105-7 and 105-8). Each of these options provided an irregular edge for tissue contact wherein electrical charge would accumulate (Narayan et al, 1996). Whereas all were conceptually slightly different, working elements were easily fitted to existing equipment with fairly similar results.

The technology was updated in the late 1990s, and procedures are now customarily done with bipolar current, allowing the use of iso-osmolar solution as irrigant. The use of bipolar current concentrated the current at the end of the instrument as described earlier in the B-TURP section. Initial bipolar vaporizations were done with the Gyrus (now part of Olympus) Axipolaire, which was a nonrotating element that was an 80:20 platinum-iridium alloy

that was separated from the stainless steel return electrode by a ceramic insulator. This operated by forming a vapor pocket at the tip of the device, which had a high temperature. When this pocket was brought into contact with the prostate tissue, vaporization would occur, but the electrical circuit would be completed with the low-impedance saline allowing the active electrode to arc to the return electrode. Current was not required to pass through the patient, and deeper tissue heating would not occur.

Currently, Olympus markets the updated variation of the bipolar technology that uses PK technology. The PlasmaButton electrode (Fig. 105-9) uses a half-spheric shape that provides a large surface area for current accumulation. Plasma is generated in a similar fashion to that described in the B-TURP section. However, because of the large surface area of the working element, tissue contact is almost always required to create the orange corona.

Unlike with other TURP alternatives, general or regional anesthesia is typically required. Because all tissue is vaporized, no pathologic specimen is available for examination.

Technique

Preoperative. In general, the procedure is done using general or regional anesthesia. Once this has been established, the patient should be carefully placed into the dorsal lithotomy position with

all pressure points carefully padded. Adequate antibiotic coverage should be given and a standard skin preparation should be used. A grounding pad will be required for a monopolar approach but is unnecessary if a bipolar technology is used. Appropriate irrigating fluid should be maintained at body temperature and placed at a height that allows adequate visualization without compromising patient safety.

Intraoperative. As described by Kaplan and Te (1995), the operative technique is similar to standard TURP. Standard transurethral resection equipment is used. The major difference is the use of a specially designed electrode for vaporization, which replaces the standard loop TURP electrode. This technique was originally described with the VaporTrode and required a nonionic solution because it was a monopolar technology. The VaporTrode is a spheric electrode on a transverse-oriented axis that will roll as it is drawn along tissue. This allows continuous contact with tissue. The Olympus PlasmaButton electrode has replaced this in many urologists' armamentaria because this technology allows the procedure to be done with normal saline irrigation. The PlasmaButton electrode has a half-moon shape that provides a large surface area for contact with tissue but without the moving parts of the VaporTrode.

As always, the scope and moving pieces should be examined and checked before being placed into use. An obturator is usually used to place the resectoscope sheath. The bladder should once again be examined for any pathology before beginning; the location of the ureteral orifices and verumontanum should also be identified.

Although alternate strategies certainly exist, the initial technique is described here. **The cutting current is used for vaporization, and the fulguration current setting will lead to tissue coagulation.** Common monopolar power settings are 200 to 240 W for cutting current and 60 W for coagulation. The bipolar technology uses settings of 280 W and 140 W.

In this technique, the surgeon begins by vaporizing the middle lobe from the bladder neck to the verumontanum (between the 5 and 7 o'clock positions). This will open a large channel for fluid irrigation and continued visualization. The vaporization is accomplished with overlapping sweeps of the electrode that simultaneously deepen and widen the channel. The depth of the treatment remains the same; visualization of the white fibers of the surgical capsule marks the desired depth of vaporization.

Once a sufficient channel has been opened for irrigation flow, the lateral lobes are then vaporized starting at the 1 o'clock position to the 5 o'clock position and moving in a clockwise fashion. The urologist should encounter minimal bleeding with this technique, with any hemorrhagic area controlled at the time of identification. Use of the electrode to place pressure on the bleeding area with use of the coagulation setting is very effective. The coagulation setting uses a lower-energy setting and will coagulate tissue with minimal further vaporization.

After the left lobe has been completed, the right lobe may be vaporized starting at the 11 o'clock position and moving counterclockwise down to the 7 o'clock position. This will complete all but

the anterior area of the vaporization. The volume of irrigant in the bladder will often change the surgeon's perspective on the magnitude of the cavity in the prostatic fossa because a full bladder will naturally pull the prostatic fossa open. When vaporizing the anterior portions of the prostate, one may find that this is easier with a bladder at a lower overall volume.

Vaporization of tissue around the prostatic apex can be a problem during the procedure, with concerns of energy advancing beyond visualization and causing sphincteric injury. The risk of sphincteric injury must be balanced against the risk of symptom recurrence; avoidance of sphincteric injury is paramount. Owing to these difficulties and fear of unrecognized vaporization depth, one group described a hybrid technique of resection of apex tissue with fulguration of the resected bed afterward. Although economically less sound because of the use of two electrodes, this is a possible approach (Tefekli et al, 2005). Once hemostasis has been controlled, the scope can be removed and a Foley catheter is placed. The catheter should be irrigated and the return of clear to light pink irrigation fluid should be confirmed before terminating the procedure.

Postoperative. Patients can expect the catheter to be removed within the first 24 hours. We commonly remove this in the morning of the day after surgery as long as there is minimal bleeding and no unforeseen intraoperative complication occurred. Patients should be able to void shortly thereafter. Some authors have performed the procedure as a same-day discharge procedure because of the improved hemostasis (Eaton and Francis, 2002). Convalescence should be fairly rapid; however, trauma or pressure to the perineum should be avoided with similar instructions as those given to patients undergoing TURP. An eschar or other solid tissue mass may be passed around 7 to 14 days after the operation.

Outcomes. Outcomes for both the monopolar and bipolar studies are presented in the following paragraphs. **Overall, initial results of monopolar TUVF were similar to TURP, with a decrease in some adverse events. Long-term durability came into question, and enthusiasm for TUVF waned toward the late 1990s to early 2000s. The update to the bipolar technology renewed some interest in the technique, and although long-term durability is untested, it is a promising improvement.** However, in almost all studies, maximum prostate volume is limited to 70 to 80 g, making the applicability of the technology to large glands unknown.

Animal and in Vitro Studies. A canine model examining the grooved rolling cylinder (Richard Wolf Medical, Vernon Hills, IL) provided some basic understanding of coagulation depth and peripheral heating (Perlmutter et al, 1995). Perlmutter and colleagues found that multiple passes in the same area did increase the depth of coagulated zone (78% deeper than a single pass). Temperatures at the neurovascular bundle and rectal wall were unchanged by the procedure, and a 2°C rise was noted at a distance of 6 to 7 mm from the fossa cavity. The prostate capsule measurements were 5 mm from the edge of the vaporization margin, and a 4.3°C increase was noted there. Wattage was noted to increase both coagulation depth and width when applied to the canine liver during the same study. In general, coagulated tissue was not seen deeper than 2 to 3 mm from the prostatic fossa cavity. The largest change in temperature was noted in the irrigating fluid, which the researchers concluded acted as a heat sink during the procedure.

Chronic histopathologic changes in the prostate after vaporization were defined by Benjamin and colleagues (1997). Throughout the healing process, no extension of the initial 2-mm necrotic area occurred. Re-epithelialization of the fossa was ongoing by the third week after surgery, with epithelial stratification at 5 weeks.

Single-Cohort Studies. Kaplan and Te (1995) reported on their first 25 patients treated with VaporTrode. Initial results were encouraging, with significant changes in AUASS (17.8 to 4.2) and Qmax (7.4 to 17.3 mL/sec) at 3 months. Improvements in these values were seen at 1 week, and the catheter was removed at a mean of 14.6 hours from the end of surgery. All 14 patients who had erections preoperatively had retrograde ejaculation after the procedure, but the lower cost associated with a shortened hospital stay encouraged more study. Kaplan and Te reported on their first 114

patients in 1998 (Te and Kaplan, 1998) and had data out to 18 months in some patients. AUASS and Qmax changes were durable to at least 12 months. No patients required transfusion, and a mean hemoglobin decrease of 1.7 g/dL was reported. A high percentage of patients (89%) had their catheter removed within 24 hours, and although there was no increase in erectile dysfunction (ED) incidence, 84% of patients reported retrograde ejaculation. Other early adopters reported similar results (Narayan et al, 1996).

Studies naturally evolved into RCTs comparing TUVF with TURP until Botto and colleagues (2001) reported on the use of bipolar vaporization. A Gyrus system (now part of Olympus) was the first to use bipolar vaporization; the electrode had a riverboat-wheel type of configuration. At 3 months, 42 patients reported a decrease in mean AUASS from 19 to 9 and an increase in mean maximum flow from 7.9 to 19.7 mL/sec. Urethral stricture occurred in 2 patients, and 4 patients reported dysuria. Bladder irrigation was required in one patient for up to 3 days, but no transfusions and an overall low risk of bleeding were reported.

Dincel and colleagues (2004) reported on 20 patients who underwent vaporization using the PK Tissue Management System (Olympus) with an older electrode. Improvements in AUASS (72%), QoL score (61%), and Qmax (111%) were noted. Prostate volume and PSA both decreased by a little over 50%, confirming significant tissue removal with the procedure. By measuring size and operating room time, the researchers were able to calculate an average of 2.8 minutes for each gram of prostate vaporized.

The contemporary mushroom-shaped PlasmaButton electrode (Olympus) was reported on by Reich and colleagues (2010). No major intraoperative or postoperative complications were noted in this initial report. No clinical signs of fluid absorption were noted, and in the 12 patients for whom breath ethanol technique (Cumings et al, 1995) was used, no patient demonstrated an increase in ethanol concentration, implying minimal fluid absorption. Thirteen percent of patients continued platelet inhibitors throughout the procedure. Decrease in hemoglobin was minimal (1.1 g/dL). No transfusions were needed, although 53% of patients needed postoperative irrigation and 1 patient continued on the catheter for 8 days because of hemorrhage. Improvements in AUASS (61%), Qmax (174%), and PVR (77%) were all significant. One patient needed to be converted to TURP because of bleeding. This patient had a large gland (>100 g) and was among the first 5 patients treated in the study.

The single-center Zurich experience described the results of this technology in 83 consecutive patients (Kranzbuhler et al, 2013). Each patient had a preoperative mean Qmax of over 10 mL/sec, which is atypical for LUTS and BPH treatment studies. This increased nonsignificantly to 14 mL/sec directly after catheter removal. After 6 weeks, all functional outcomes (AUASS, QoL score, PVR) improved significantly when compared with baseline values, with further improvements in AUASS and QoL score at 6 months compared with the 6-week values. The PSA reduced by an average of 60% at 12 months. In one patient with a large prostate (110 mL), a conversion to B-TURP was necessary because of obscured visualization by bleeding. Many patients (31%) were on antiplatelet medications during the treatment.

Comparative Studies

Monopolar Studies. Six early RCTs of monopolar vaporization and resection with 1 year of follow-up were analyzed by Hammadeh and Philp (2003). They were able to analyze more than 200 patients in each group and found essentially identical changes in AUASS (–73% in both groups) and Qmax (216% with TUVF, 191% with TURP) between the different techniques. Complication profiles were fairly similar, although this was better studied by Poulakis and colleagues (2004). This study included patients anywhere within the first year of follow-up and compared occurrence of complication rates. The researchers found that TUVF had an improved profile compared with TURP with respect to operative duration, catheterization time, hospital stay, blood transfusion, and clot retention. Re-intervention for LUTS and BPH and postoperative urinary retention were less likely to occur in the TURP group.

Of these six early trials with 1-year follow-up, the study by Galucci and colleagues (1998) included only patients with obstruction on preoperative UDS. At 3 months post-procedure, 92.5% of the TURP group was unobstructed by UDS standards, with 88.6% of the TUVF group unobstructed. A small percentage of the TUVF group (1.4%) was still obstructed on UDS and underwent TURP; no patient in the TURP cohort was obstructed on follow-up UDS. Similar changes were noted in AUASS, Qmax, detrusor pressure at maximum flow rate (PdetQmax), and PVR between groups. However, a surprising 18.6% of the TUVF group had transient stress urinary incontinence, with 5.7% of the total cohort having true stress urinary incontinence at 12 months after surgery. This surprising presence of incontinence was attributed to a possible unseen depth of coagulation near the apex that was unanticipated by the surgeon.

While TUR syndrome was still a possibility because of the use of hypo-osmolar fluid, a study using ethanol-labeled glycine as the irrigant showed that vaporization led to less (672 mL) fluid absorption than resection (1347 mL, $P < .005$). This was thought to be a result of the sealing effect of vaporization techniques on the prostatic sinuses and vessels.

Another of these six early trials followed patients to a total of 5 years after randomization to M-TURP or TUVF (Hammadeh et al, 2003). A total of 53 of the original 104 patients were analyzed. Both groups had statistically improved AUASS, QoL score, PVR, and Qmax compared with their respective preoperative values. Although there was no statistical difference between groups at 5 years, trends toward an advantage with TUVF could be seen.

An RCT with 10-year results from patients undergoing TURP, contact laser prostatectomy, and electrovaporization was published in 2010 (Hoekstra et al, 2010). Whereas 91% of patients could be accounted for, only 44% of the original 150 patients were available for analysis. Only TURP still had a statistically significant improvement at 10 years with regard to maximum flow rate and PSA. The TURP and contact laser prostatectomy groups had prostate volumes roughly equal to the prostate volume at study start, but the vaporization group was noted to have an increase at the 10-year mark compared with the baseline value (43 g from 28 g, $P < .05$). Although failure rates were not statistically different, TURP had a failure rate roughly half that of vaporization and contact laser prostatectomy.

Bipolar Studies. Multiple studies compared the newly available bipolar vaporization technology to M-TURP in RCTs. Reports on PK technology at 12 months (Karaman et al, 2005) and then at 36 months (Kaya et al, 2007) found a decrease in operating room and catheterization time, and although no patients in the bipolar group required transfusion, two TURP patients did. AUASS improvement was statistically better in the vaporization group, although the TURP group had an uncharacteristically modest change in AUASS (only 45% reduction). The early results seemed to favor bipolar vaporization, but the 36-month results were less favorable. Although a bias related to follow-up could certainly be a factor in this change, with only 40.5% of TURP patients and 65.8% of TUVF patients analyzed, results were heavily in favor of TURP. At 3 years, TURP had improved AUASS (–74%) and Qmax (263%) compared with TUVF (–64% and 140%, respectively). Three patients in the vaporization group required re-treatment for BPH (one in the TURP group), and the patients in the vaporization group were overall less satisfied with treatment (48% vs. 60%, $P = \text{NS}$). Differences in ED and retrograde ejaculation rates were not significant.

The higher rate of complications with greater clinical efficacy was also noted by the higher recatheterization rate in the bipolar group (30% vs. 5%), with clot evacuation (19% vs. 0%) more often needed in the TURP group (Dunsmuir et al, 2003). Change in hematocrit was greater and more irrigation was required in the M-TURP group in the results of Hon and colleagues (2006). Although no difference in systemically absorbed fluid was noted, four M-TURP patients required transfusion compared with no vaporization patients ($P = .02$).

The use of the TURis vaporization seemed to further improve the results when compared with M-TURP. The single-center report from

Geavlete and colleagues (2010) found that the PlasmaButton system led to a better improvement in AUASS, QoL score, and Qmax with less significant hematuria, transfusion, and clot retention compared with M-TURP at 6 months. In their report at 18 months (**Geavlete et al, 2011**), they also included a B-TURP group. The bipolar vaporization group fared better than either TURP group with regard to capsular perforation, operating room time, and catheterization time. Outcomes such as postoperative AUASS, QoL score, and Qmax were equivalent among all groups at the 18-month point, with all groups improved compared with baseline.

Complications

Intraoperative and Perioperative. It appears that the simultaneous vaporizing and coagulating properties of the vaporization technology leads to an overall decreased risk of intraoperative bleeding risk. There is **less blood loss** (**Kupeli et al, 2001**), although the overall low risk of **transfusion** in most RCTs makes a statistical difference difficult to achieve; a range of 0% to 2% was seen in a systematic analysis of RCTs (**Ahyai et al, 2010**). Other intraoperative complications such as **capsular perforation** or **conversion to TURP** are also rare, with conversions to TURP for bleeding seeming to occur more frequently in larger glands (**Kranzbuhler et al, 2013**).

Postoperative. The largest postoperative risk associated with TUVF is the **need for re-treatment** for LUTS and risk of unplanned **postoperative recatheterization**. The meta-analysis by **Ahyai and colleagues (2010)** found that 8.2% of patients required recatheterization after TUVF, which was among the highest rates of the analyzed techniques. The increased hemostasis achieved intraoperatively appears to lead to a decreased postoperative risk of **clot retention** (**Geavlete et al, 2010**).

The inability to accurately judge the depth of energy dispersion led many early adopters to be concerned about inadvertent coagulation, particularly around the apex. Although not statistically significant, the slight increase in **incontinence** compared with TURP seen in the review by **Hammaddeh and Philp (2003)** may be a product of the energy dispersion. Although still not rigorously studied, the increased risk of new **ED** (12% vs. 5%) when compared with TURP also increased the concern of unwanted depth of coagulation. The risk of postoperative dysuria also appears to be more common in TUVF (**Ahyai et al, 2010**).

As described in the B-TURP section, the TURis or TUVis system uses the outer resectoscope sheath as the return electrode. In a study looking at the use of this system, a small series of calamitous complications was noted. In three consecutive patients, one patient had **bladder necrosis** leading to severe storage symptoms and two patients had complete **urethral necrosis** with resulting urethrocucutaneous fistula (**Robert et al, 2012**). Our preference is for use of the PK system as opposed to the TURis or TUVis system.

Conclusion. Prostate electrovaporization continues to be a viable option for treatment of LUTS caused by BPH. Results are comparable to TURP with regard to improvements in voiding symptoms. Although prostate electrovaporization initially was a very popular option for treatment of LUTS and BPH, widespread acceptance was likely tempered by questions about durability with a concern about dysuria and re-treatment rates. The excellent hemostasis of the procedure leads to excellent intraoperative visualization. While this was a significant innovation in its time, it appears that laser vaporization is likely to supplant it as the preferred form of prostate vaporization.

procedure times. This process is supported by the fact that prostates with a more significant vessel density are less likely to respond well to treatment in general (d'Ancona et al, 1999a).

Mechanism of Action. The mechanism by which TUMT causes the reduction in LUTS caused by BPH is **not completely understood**. Multiple theories exist and are not mutually exclusive. These theories focus on altering prostate innervation or morphologic tissue changes in the prostate.

Nerve Degeneration and Sensory Changes. The first of these theories rests on the **dynamic concept of prostatic obstruction** wherein the tone of the smooth muscle of the prostate causes obstruction. This has been studied by investigators by examining tissue after TUMT wherein a biopsy was obtained. Ten patients underwent OP after TUMT; specimens were evaluated using histologic immunohistochemical stains. The urethra was well preserved; compared with controls, the specimens were found to have "disrupted" nerve fibers; with axons rarely being found. The authors suggested that thermal damage to the adrenergic fibers essentially induced a "long-term α -blockade" (Perachino et al, 1993). This theory has few adherents.

The denervation may also be specifically targeted to the smooth muscle fibers of the prostate. A carefully controlled study using a prostate chip taken at the beginning of the procedure was stained using a nonspecific neuromarker protein gene product in both a control group of 10 patients and in 10 patients who had undergone TUMT a week before. Stained fibers were seen in all layers of the control biopsy specimens. Almost all of the study group biopsy specimens had nerve fibers in the lamina propria and epithelial layer. However, all but one study group specimen showed an almost complete absence of nerve fibers in the smooth muscle layer. The TUMT-treated patient without the smooth muscle nerve fiber changes had a small prostate (20 g). The findings of a preferential smooth muscle destruction of muscle fibers were noted even without a large degree of necrosis in the specimen (Brehmer et al, 2000). Whereas the aforementioned study noted changes in only

some nerve fibers, there is still the possibility of a later-onset denervation of the other fiber groups. Animal studies looking at heat treatment of dog sciatic nerves found almost no histologic changes immediately after a heat treatment similar in duration and temperature of TUMT. However, segmental demyelination and axon loss were noted 3 weeks later, with changes persisting out to a year (Vujaskovic et al, 1994).

A more specific look at the subgroup of nerve fiber destruction in TUMT was completed by a group binding assay specific for the α_1 receptor. Twenty-five patients were included. Ten of these patients received TUMT before the cold-punch biopsy and then subsequent TURP. Five patients had TUMT then retropubic prostatectomy. The control group underwent TURP ($n = 10$). A **statistically significant difference in the mean α_1 -adrenergic receptor density was found between the control (96.4 fmol/mg) and the TUMT-treated group (71.3 fmol/mg)**. The receptors in all groups continued to have a similar dissociation constant (ability to bind their ligand) (Bdesha et al, 1996).

In an interesting study using electrical stimulation to examine the prostatic urethra in 13 patients before and after TUMT, the large majority of patients had improvements in symptoms, with the most favorable effect noted in storage symptoms (nocturia primarily). The decrease in urinary urge effectively was parallel to the increase in sensory threshold. The authors postulated that the decreasing prostatic urethral sensation may lead to decreased input in the urethra-detrusor excitatory reflexes with an overall improvement in perception of voiding symptoms (Brehmer and Nilsson, 2000).

Morphology Changes. When heat is applied to a specific portion of the prostate to a sufficient temperature and duration, an **area of necrosis is created**. This area of necrosis eventually contracts to form a scar and reduces overall prostate volume. In a study looking at heat gradients in the prostate and histologic effects, patients underwent TUMT, followed by surgical tissue retrieval at varying later times. During the microwave procedure, temperature mapping was performed at multiple prostatic sites using fiberoptic thermosensors. Microwave treatments resulted in peak prostate temperature of 80°C with penetration of heat deep into the prostate parenchyma. Histologic changes were related to temperatures in the prostate. Mean temperatures increased rapidly with radial distance from the urethra to a maximum of 54°C at a distance of 0.5 cm from the urethra. As temperature increased beyond this distance from the urethra, temperature decreased exponentially but remained above 45°C at a distance of 1.6 cm radially. Pathologic findings were similar in all specimens, with sharply circumscribed intraprostatic hemorrhagic necrosis at sites where 60 minutes of a minimum of 45°C was elicited by treatment. The borders of the areas of necrosis and the viable tissue were sharply demarcated. The mean range of this border was from 0.5 to 2.5 cm from the urethra with a mean distance of 1.6 cm. The researchers also did note, but poorly explained, an area of devitalized but noninflammatory tissue between the necrotic and normal areas (Larson et al, 1996).

A similar study explained this area between necrotic and normal tissue. Patients exposed to TUMT had an area of necrosis in a discrete area 20 to 25 mm from the urethra in the prostatic tissue. Within the area surrounding the necrosis, widespread apoptosis was noted (Brehmer, 1997). The root cause of the apoptosis could not be elicited in that study, but other work has shown that cell death results from apoptosis then necrosis based on an increasing heat load applied to the tissue (Harmon et al, 1990). Cultured prostatic stromal cells exposed to moderate hyperthermia of only 47°C for an hour confirmed the possibility of heat-induced apoptosis; 76% of cells were apoptotic. Cells also did undergo necrosis (14% of the sample), which further solidifies that there is a "thermal load" at which cells preferentially die of necrosis or apoptosis (Brehmer and Svensson, 2000). The **reduction in prostate volume appears to be related to the energy platform used; the low-energy protocol decreased size by only 14%, whereas higher-energy protocols decreased size by 25%** (Devonec et al, 1993).

Technique

Preoperative. The benefit of a MIST selection is the ability to perform the procedure in the office, typically using just local

anesthesia. As always, the patient's ability to tolerate the procedure should be considered. Overnight admission is not needed, and patients are usually sent home directly after recovering from the procedure. Cystoscopy is required before TUMT because the **presence of a median lobe is an exclusion criterion.** The median lobe would not be treated during the procedure, and its presence may also direct the catheter away from the midline, altering the treatment. The prostatic length must be measured during the cystoscopy. A prostatic length of less than 25 mm is not suggestive of an enlarged prostate and would make the procedure technically challenging and perhaps unsafe. Prostate size should be 30 to 100 g for TUMT.

Contraindications to the procedure include implanted pacemakers, defibrillators, inflatable penile prosthesis, artificial urinary sphincters, and metal implants in the pelvis such as a total hip replacement. Patients with urethral strictures should also be excluded from treatment because the catheter may be difficult to place and the correct position may be difficult to verify. Patients who have undergone previous invasive BPH treatment should also be excluded because this is an untested group and there may be unexpected projection of microwaves into aberrant locations. Comorbid conditions such as peripheral arterial disease with claudication, prostate cancer, bladder cancer, and underlying neurologic disorders should also lead the patient and surgeon to choose a different treatment method.

Intraoperative and Perioperative. The specialized catheter is inserted per urethra and advanced into position. The anterior wall of the rectum is monitored by the placed rectal thermometer probe. The preset program can then be started, with an automated program running for the duration of the procedure and monitoring urethral and rectal temperatures. The balloon of the catheter remains in the bladder, keeping the catheter in place while the EM waves are emitted into the transition zone of the prostate (Fig. 105-11). One role that the surgeon plays in this procedure is to provide occasional "vocal" anesthesia to the patient in the form of calming the patient and providing reassurance to an awake patient. Continuous monitoring of patient comfort is critical. Unexpected discomfort may imply misplacement of the catheter. Significant injuries have occurred when such advice is not heeded.

Postoperative. A benefit of TUMT is the benign postoperative course. Perioperative complications are unlikely and patients do

not require hospital admission. Patients may return home directly from the procedure, and convalescence is rapid. **Postoperative catheterization for a period of days is almost certain** with previous generations of TUMT but is becoming less common. Higher energy platforms have led to an overall lower rate of the standard transient postoperative urinary retention, but patients should be carefully counseled about this risk.

Outcomes. Thermotherapy or microwave therapy continues to be a treatment for BPH owing to the relative ease of use and ability to be done as an office-based procedure. Because of the many different technology platforms, trials are difficult to group into larger analyses. **In general, the studies available are very heterogeneous and are frequently single-cohort and noncomparative trials having short-term follow-up; they should be judged carefully and individually.** An obvious lesson learned from these trials is that the higher-power systems have superior results compared with their lower-power predecessors.

Predicting Outcomes. Initial work published on predicting outcomes of TUMT focused on the Prostatron 2.5 platform. This work defined early cutoff points to help guide the urologist in the care of patients after TUMT (d'Ancona et al, 1999a). **Outcomes were evaluated at 6 months, limiting the long-term scope of the study, but good response was independently predicted by preprocedural variables such as younger age at treatment, larger prostate volume, and higher grade of BOO.** The energy used on the prostate during the procedure was also predictive of response but has less usefulness because it is post priori. Because PSA is a surrogate for prostate volume, pretreatment PSA was also found to be helpful in predicting outcomes in some studies (Djavan et al, 2000) but not in others (Laguna et al, 2002).

Ability to predict outcomes based on initial AUASS has been more difficult. In one controlled study the proportion of patients achieving an AUASS of less than 9 (mild symptoms) was similar among patients in both the moderate and severe symptoms groups. Of the patients in the moderate symptoms group, 50% migrated to the mild group, many patients stayed in the moderate group (38%), and some worsened to the severe group (12%). Of those already in the severe group according to pretreatment AUASS, 14% continued to have severe symptoms while many patients improved to the moderate (36%) and mild groups (49%) (Larson et al, 1998). Because many urologists may prefer this treatment in patients at higher risk of surgery, the usefulness in higher-risk patients has also been studied. In a study of an HE-TUMT device, the treatment was equally efficacious in high (3 or 4) or low (1 or 2) American Society of Anesthesiologist (ASA) scores (d'Ancona et al, 1999b) with no differences in post-treatment catheterization or ability to tolerate the procedure.

Single-Cohort Studies. Despite the ease of use and relatively low complication rates, the major concerns with TUMT are the reduced overall LUTS improvement compared with other treatment options and the lack of durability. One vexing study using an older, low-energy transurethral microwave therapy (LE-TUMT) machine (Prostatron 2.0) demonstrated initial significant improvement in patient level of satisfaction with treatment (Hallin and Berlin, 1998). However, over the 4-year period there was a progressive, marked decrease in the number of satisfied patients from 62% at 1 year to only 23% at 4 years. The initial improvements in symptoms and increase in flow rates were followed by reversal of these findings at the 4-year follow-up. In addition, two thirds of the patients in the study received additional BPH treatment within the 4 years for which they were followed. These concerns were further justified when studies showed a cumulative risk of subsequent TURP re-treatment of 40.5% at 5 years of follow-up, and a percent cumulative risk of any re-treatment (including α -blockers) of 57% (Keijzers et al, 1998). Another LE-TUMT protocol confirmed the high re-treatment rates, with 35% of patients requiring additional treatment within 3 years (Daehlin and Frugard, 1999). Studies of early, low-energy systems looking at changes in both subjective and objective measures of improvement have found varying results. Almost all of the low-energy studies showed an improvement in subjective symptom scores, but often without

Figure 105-11. Transurethral microwave therapy catheter treating the transition zone of the prostate. (Courtesy Kevin T. McVary.)

changes in objective measurements such as maximum flow, residual urine, or UDS features such as peak detrusor pressures. With the upgrade to high-energy (HE) devices, changes in objective metrics became more common. Although more energy is used, the high-energy protocols are still well tolerated under local anesthesia (Eliasson and Wagrell, 2000). When heat-shock protocols are used, the shorter duration of treatment also leads to an increased initial pain score but a similar post-treatment pain score (Francisca et al, 2000).

Using an HE-TUMT device (Targis), a group of investigators demonstrated significant improvement in AUASS, QoL score, Qmax, and PVR that was durable at 24 months (Thalmann et al, 1999). UDS was routinely performed in patients, and improvements in mean detrusor opening pressure and detrusor pressure at maximum flow were also significantly improved 6 months after treatment. A cavity in the prostatic fossa (similar to those seen in patients after TURP) was noted in 77% of patients, and TRUS demonstrated a decrease in prostate volume from 57.6 to 42.4 mL. Despite these positive results, 13% of patients required re-treatment.

In a recent TUMT study, the findings of many previous studies were reiterated (Mynderse et al, 2011). The Cooled ThermoCath catheter with a Targis system was used under a 30-minute heat-shock protocol. The percentage of patients requiring any sort of postoperative catheterization (50%) was less than in previous TUMT studies, and only 3% of patients required catheterization for more than 7 days. At the final follow-up at 5 years post-treatment, a 43% improvement in AUASS and 39% increase in Qmax was noted. Unfortunately, 29% of patients required additional BPH-related treatment; 9% of the overall cohort required surgical treatment.

To summarize symptomatic improvement with HE-TUMT, patients will have a 60% reduction in symptom scores noted at 3 months of follow-up. This tends to become slightly better at the 6- and 12-month points. There is no significant difference among HE-TUMT devices in the reduction in symptoms. At 3 years, symptom improvements worsen to only 45% improvement, but re-treatment is seen in close to 20% of patients (Floratos et al, 2001). The aggregated changes in Qmax represent a 50% improvement seen at 3 months and stability at 12 months (Gravas et al, 2003), with studies rarely reporting a post-treatment Qmax greater than 15 cm/sec.

Patients with urinary retention represent a more challenging BPH group to treat. In one of the first HE-TUMT studies of men with AUR, 94% of men were able to spontaneously void at 4 weeks after treatment (Djavan et al, 1999c). Although no pressure-flow studies were obtained, this group likely represents a cohort with functional detrusor muscle. Contrary to this, in a study that included chronic urinary retention patients, the 1-year failure rate was 25% and the mean catheterization time was 38 days (Floratos et al, 2000). In a study of surgically high-risk patients with AUR, 87% were able to void spontaneously (3 months post-procedure), and 7.3% experienced repeat urinary retention within 2 years (Berger et al, 2003).

Comparative Studies

Transurethral Microwave Therapy versus Sham. Many sham-controlled studies involving TUMT have been performed. This is likely because of the low morbidity of producing a sham equivalent arm, as minimal anesthesia is required. These sham studies are interesting in that they highlight the placebo effect present in BPH treatment. The placebo effect of a sham study was most notably highlighted by Nawrocki and colleagues (1997). In this study, patients were randomized to one of three groups—TUMT, simulated TUMT, and observation—with 6-month follow-up. The simulated TUMT group underwent a process identical to TUMT except the generator ran a simulated program that included machine noise, screen readouts, and heat emission by a pad placed under a blanket. No statistical changes were noted in objective measures such as pressure-flow outcomes or urodynamic variables. Surprisingly, there was a statistically significant decrease in AUASS for both the TUMT (19 to 9.5) and simulated TUMT group (17.5 to 9.5). The untreated group did not note this change (AUASS changed

from 18 to 17). These results are interesting in that they highlight the perceived benefits of TUMT (in terms of reported AUASS changes seen in both the TUMT and simulated TUMT group) but showed no objective changes in any of the groups. Merely performing a sham treatment reduced AUASS in a significant fashion.

Other prospective sham studies (without untreated groups) did show improvements in peak flow to complement the decrease in AUASS. Studies of the Targis thermoablation system (Urologix) (Larson et al, 1998) and Dornier Urowave system (Dornier MedTech, Munich, Germany) (Roehrborn et al, 1998b) both exhibited this response with overall similar findings. The Dornier Urowave system provided decreases in the AUASS for both the treatment and sham groups. Treatment group AUASS decreased from 23.6 to 12.7 at 6 months, with a decrease of 23.8 to 18.0 in the sham group. Although both study groups had a significant decrease, the change in the treatment group was statistically superior. Peak flow rates were improved in the treated (7.7 to 10.7 mL/sec) and untreated groups (8.1 to 9.8 mL/sec), with improvement in the treated group being statistically superior.

The study of the Targis system had a similar pattern of findings. Both the treatment and sham groups had statistically significant improvements in AUASS—a mean decrease from 20.8 to 10.5 in the treatment group and a lesser, but still significant decrease in the sham group (21.3 to 14.3). Flow rates improved from 7.8 to 11.8 mL/sec in the treated group, with a less impressive increase occurring in the sham group (7.8 to 9.8 mL/sec) (Larson et al, 1998).

Transurethral Microwave Therapy versus α -Blocker. Some authors have stated that on the continuum of BPH treatment, TUMT should stand between medical management and more aggressive treatments such as TURP and OP (Djavan et al, 1998a). The underlying precept for this view is that the single, low-risk procedure could remove the hassle and cost of years of medical treatment. Although patients undergoing TUMT do have a frequent need for additional BPH re-treatment, the results are not far different from those in patients in whom medical management fails. In an investigation of re-treatment in patients using α -blockers, results were assessed at 3 years; failure rates of 27% (tamsulosin), 37% (alfuzosin), and 49% (terazosin) were noted (de la Rosette et al, 2002). One RCT compared TUMT with α -blocker therapy (terazosin). Mean AUASS and Qmax were improved for both groups; TUMT had a more pronounced effect at both 6 and 12 months. TUMT resulted in a 35% improvement in AUASS compared with α -blockers, and a 22% improvement in Qmax. The terazosin group had a sevenfold higher actuarial treatment failure rate (Djavan et al, 2001). However, the definition of failure was qualitatively different between groups, and the findings should be interpreted cautiously.

Transurethral Microwave Therapy versus Transurethral Resection of the Prostate. Concerns about the durability of TUMT are common despite the improvement seen in uncontrolled studies and sham comparisons; many studies had higher than acceptable re-treatment rates, with TUMT often failing only months after surgery. As always, comparison to the gold standard treatment is necessary before any treatment is considered a standard practice. Whereas changes in the energy delivered by the system improved many patient outcomes, comparison to TURP further highlighted the weaknesses of the TUMT intervention.

A randomized trial using the HE-TUMT Prostatron 2.5 system included 6 months of follow-up (Ahmed et al, 1997). The primary end points for the study included AUASS, maximum flow, residual urine, detrusor pressure at maximum flow, and prostate volume. All outcomes in the TURP group were improved. The TURP group had improvement in all outcomes, but in the TUMT cohort, only the AUASS was improved and multiple other factors worsened. In general, the incidence of adverse events was higher with TURP, but the TUMT group had prolonged postoperative retention.

Contemporary studies of the same machine had very different results. At 1 year of follow-up there was a decrease of 78% in the Madsen-Iversen symptom index in the TURP group; a decrease in the TUMT group was also noted (68%). Maximum flow rate

improved by 100% (TURP) and 69% (TUMT), and both groups had relief of bladder outlet symptoms by urodynamic parameters. Although the effects in the TURP group were pronounced in all accounts, they were not statistically different than the TUMT group. Groups were equivalent with regard to need for re-treatment, but the TURP group needed more frequent returns to the operating room for coagulation (three vs. zero patients). The TUMT group had a longer duration of catheterization, with one patient requiring 35 days. Correspondingly, the TUMT group had an increased risk of postoperative UTI, with one patient requiring readmission to the hospital for infection. In addition, postoperative irritative symptoms were more common in the TUMT group (29% vs. 14%) (d'Ancona et al, 1997).

A similar randomized study with longer follow-up (median 33 months) displayed improvements in the TUMT group with respect to urinary flow (improved 64%) and AUASS reduction (–60%), although these paled in comparison to those in the TURP group (+214% in Qmax and –85% in AUASS). With a longer follow-up the re-treatment rates in this study should be carefully examined. A re-treatment rate of 19.8% in the TUMT group and 12.9% in the TURP group were not statistically different ($P = .28$); however, the reasons for re-treatment appeared to have different causes. In the TUMT group, 10 of the 14 patients underwent additional BPH treatment (TURP, laser prostatectomy, transurethral needle ablation of the prostate [TUNA], α -blockers), whereas only 1 of the 8 patients in the TURP group required this type of re-treatment (α -blockers). Although there was no statistical difference in the number of patients undergoing re-treatment, it appeared that the TUMT group was more likely to need re-treatment for residual BPH (Floratos et al, 2001).

More recently a multicenter, randomized trial released 5-year follow-up results to complement the previously released results at 1 and 3 years. At the initial 12-month follow-up the researchers concluded that there was no statistical difference among treatments with regard to Qmax, detrusor pressure, and prostate volume; however, the change in each of these was more pronounced in TURP patients. A longer postprocedural catheter time (14 vs. 3 days) was seen in the TUMT group. Adverse events were graded according to severity, with the TUMT group undergoing more mild or moderate events (often characterized as “expected”) and the TURP group having more “serious” events (e.g., clot retention requiring readmission) (Wagrell et al, 2002). The 5-year data (66% of the original patients available) showed that 16% of the TUMT patients were considered to have experienced treatment failure, but only 6% of the TURP group (Mattiasson et al, 2007). In studies using UDS to classify the obstruction, TURP proved superior. A comparison at 30 months of HE-TUMT versus TURP found that one third of the TUMT patients remained “obstructed” on UDS, whereas only 14% of the TURP group maintained this UDS classification of “obstructed” (d'Ancona et al, 1998).

A recent Cochrane review of TUMT analyzed the six trials comparing TUMT and TURP. The pooled mean AUASS of TURP decreased by 77%; a 65% reduction was seen in TUMT. The pooled mean peak urinary flow increased by 119% with TURP and by 77% with TUMT, with a weighted mean difference favoring TURP by 5.08 mL/sec (Hoffman et al, 2012). In a study comparing quality-of-life outcomes between TURP and TUMT, a 41-question assessment was completed before and after surgery. Metrics of overall well-being, urinary symptoms, sexual function, daily activities, social activities, and psychological well-being were assessed. Both treatment modalities had a significantly positive effect on aspects of life, with perception of activities of daily living along with perception of urinary difficulties improving. Although both treatments were efficacious in improving quality measures, TURP did have a greater impact than TUMT in the 147 patients examined (Francisca et al, 2000).

Complications

Intraoperative and Perioperative. Much of the argument for the use of TUMT over TURP in the treatment of BPH is the decreased complication rate, particularly in the perioperative period. Higher rates of early re-treatment for procedural complications are seen for

TURP compared with TUMT. Unfortunately, most of the TUMT trials do not have a comprehensive review of adverse events. This leads to a potential bias because those reporting may have had lower than average complication rates. In almost all cases patients are able to tolerate the procedure in an office setting. Patient reports of a sensation of local, perineal warmth or an urge to urinate are common but do not limit the ability to complete treatment. Although some practitioners may advocate sedatives or analgesics for every patient, a randomized comparison proved that topical anesthesia alone was sufficient (Djavan et al, 1998b). With careful monitoring and correct placement of the catheter and rectal temperature probe, injury to surrounding structures should not occur. Errant reports of severe complications such as penile necrosis and urethral fistulae have been seen in the U.S. Food and Drug Administration (FDA) registry but are likely a result of improper catheter placement or poor monitoring of the patient during the procedure (Walmsley and Kaplan, 2004).

Postoperative. Contrary to the perioperative profile described previously, in general the long-term complication rates favor TURP. Re-treatment rates for BPH are significantly higher for TUMT than TURP. Re-treatment rates were discussed at length earlier and will not be further elaborated on here. Complications such as postprocedural hematuria leading to transfusion are rare after TUMT. Urethral stricture and bladder neck stenosis are occasional complications with a cumulative risk of about 2% (Floratos et al, 2001). Transient incontinence is seen in about 2% of patients, with permanent incontinence being extremely rare. Post-treatment convalescence is fairly rapid, with a mean recovery at home of 5 days and with 55% of patients spending less than 3 days at home (Ramsey et al, 1997). Prolonged catheterization times and AUR with the early generations of TUMT were the rule and not the exception. Almost all studies demonstrated an increased time with catheter compared with TURP, and catheterization durations of up to 2 weeks are not unusual (de la Rosette et al, 1997).

In an effort to reduce the catheterization times and postprocedural symptoms, attempts were made to use biodegradable urethral stents (Dahlstrand et al, 1997), temporary urethral stents (Djavan et al, 1999a), and periprocedural α -blockade (Djavan et al, 1999d). α -Blockade reduced postoperative retention from 12% in TUMT alone to 2% in TUMT with periprocedural α -blockade. In a prospective comparison of α -blockers and urethral stents, stents were more effective at 2 weeks, reducing symptom scores and improving flow rates. No patient with a urethral stent had retention 1 week after TUMT (compared with 11% of patients with TUMT alone), but 11% of patients with urethral stent needed early removal because of clot formation or stent migration (Djavan et al, 1999b).

Coinciding with prolonged catheterization, UTI in the post-TUMT patient is a common finding. Reports of incidence are sporadic, but numbers as high as 13.5% (Dahlstrand et al, 1995) have been published, with most large studies reporting an incidence in the low- to mid-single-digit percentages. With higher-energy protocols, the effects on sexual function have been more pronounced. Although sexual dysfunction has not been rigorously studied with validated questionnaire data from preprocedural and postprocedural periods, few reports have high rates of this finding. One report found only 5% of patients to have new ED (Kirby et al, 1993), and 55% of patients still graded sex as “very satisfying” (Francisca et al, 1999). In the TURP cohort of this comparative study, only 21% of the TURP group gave the answer “very satisfying.”

Reports of ejaculatory dysfunction after TUMT follow a similar pattern but have also not been rigorously studied. Most reports have reported low event numbers, with many reporting no change at all. A fairly high 44% incidence was reported in one study, which stands out against otherwise benign reports (de la Rosette et al, 1996). A study dedicated to sexual outcomes found that 74% of the patients had antegrade ejaculation after the procedure (Francisca et al, 1999). In the Cochrane review of TUMT versus TURP, TUMT was associated with a decreased risk of retrograde ejaculation, stricture treatment, hematuria, blood transfusion, and TUR syndrome. TUMT did have an increased risk for dysuria, urinary retention, and BPH symptom re-treatment. (Hoffman et al, 2012).

Conclusion. TUMT is a technology that is used to apply heat to the prostate; the mechanism of action is still in debate even 20 years after its introduction. Although a technically easier procedure than many of its counterparts, it carries a **potentially prohibitive need for re-treatment** because of persistent LUTS and BPH. It does have a favorable overall complication rate compared with TURP, but the risk of eventually requiring re-treatment needs to be weighed carefully when considering TUMT for a patient. One should note that any assessment of long-term durability and measure of voiding symptoms after TUMT will suffer from a selection bias, because it will include only patients who were responders and did not advance to other treatments. **Overall, the summation of the large volume of literature on TUMT further cements the place of TUMT in the continuum of treatment for BPH.** In general, the patient will experience an improvement in symptoms that is not as pronounced as with TURP, but TUMT has an overall more appealing safety profile and avoids the inherent risks of anesthesia. The use of this technology as a replacement for medical therapy is reasonable.

Transurethral Needle Ablation of the Prostate

Overview and Concept. The TUNA system is composed of a radio-frequency (RF) generator, a disposable urethral endoscopic catheter that attaches to a reusable catheter handle, and an optics system. The treatment concept and design was originally FDA approved in 1996 and was significantly updated in 2003. The procedure was first performed in 1993 (Schulman et al, 1993). The specialized urethral endoscopic catheter is used for this procedure and is attached to a reusable control handle. This rigid scope is placed into the urethra and advanced into the prostate under direct vision. The device uses an embedded lens that is at either 0 or 15 degrees based on the surgeon's preference. Once the device is in position, needles are deployed from the end of the catheter into the prostatic parenchyma. The needles deploy at an acute angle to each other and at a right angle to the longitudinal axis of the catheter. The needles have a variable length that can be adjusted to different prostate widths and sizes. The urethra is protected from heat energy by polytetrafluoroethylene (PTFE) and nylon sheaths that extend out to cover the proximal portions of the treatment needles. The urethra is untreated and not denuded, so the patient should theoretically have minimal local symptoms. The protective sheaths also have a thermocouple that monitors the temperature at the edge of the sheath. The needles and shield are adjusted by controls on the catheter handle (Figs. 105-12 and 105-13).

As with ultrasonography, the lower the frequency generated, the greater the depth of tissue penetration of the RF energy (or sound waves in the case of ultrasound). **Low-energy monopolar**

RF has excellent tissue penetration. The RF flows into the prostate parenchyma and interacts with the water molecules in the cells. This interaction creates localized heat around the needles. The heat energy has a fairly low dissipation into unwanted tissue because the temperature decreases as the distance from the needles increases (temperature decreases by a factor of $1/\text{radius}^4$). **When an adequate amount of heat has been applied to the tissue, a spheroid area of coagulative necrosis is created, which later undergoes cavitation.** This cavitation should lead to an overall size decrease in the prostate, although there is some thought that the treatment area actually later becomes scar tissue and does not lead to a significant decrease in prostate size. Retrograde ejaculation should be minimized because the bladder neck is unaffected.

The original systems were reactive to a change in tissue impedance. The platform redesign called the Precision Plus, now marketed by Urologix, in 2003 introduced a system that **measures both temperature and impedance**. In the older, entirely impedance-based system, the generator delivered energy while the impedance of the tissue between the needles was monitored as if part of a completed circuit. The impedance increased as the tissue between the needles desiccated and was destroyed. Once the impedance reached a certain level, the treatment in this area was complete; the tissue was desiccated and no longer able to conduct current. The level of output energy delivered was operator dependent, and the rate and amount of energy delivered was vital to creating a successful lesion. If too little energy was delivered, the lesion would be small and incomplete. If the energy was delivered too quickly, tissue would desiccate too rapidly, with an inadequate total thermal load (a product of delivered energy and time), and the treatment would be less effective. The size of the created lesions was proportional to the area of tissue in contact with the needle and the quantity of energy that was delivered. In a magnetic resonance imaging (MRI) study looking at changes in prostate volume, the mean area of necrosis was 7.56 mL (constituting 11.28% of total prostate volume) (Huidobro et al, 2009).

The modern system is more straightforward. In this system, the needles have thermocouple electrodes at the tips that are able to monitor the temperature of the target tissue, and the overall tissue impedance is also monitored. Currently the only device available in the United States is marketed by Urologix.

Technique

Preoperative. TUNA is indicated in men with bothersome LUTS who are refractory to medications and have prostate sizes up to 80 g. Sterile urine should be verified before the procedure. TUNA is not recommended for patients with metallic pelvic prostheses. In addition, a defibrillator or a pacemaker may receive EM interference from the procedure, and these devices should be considered contraindications. A benefit of TUNA is that the procedure can be done with the patient under local anesthesia. TUNA can be performed safely in the office setting without postoperative admission, although a 23-hour admission is not uncommon after the procedure. The procedure should be done with a minimum of viscous urethral lidocaine, but oral or intravenous sedation (e.g., diazepam) may also be of benefit in the anxious patient. There is significant variation in the degree of anesthesia given by providers of this type of care (Bouza et al, 2006).

Preprocedural TRUS is performed to gauge the prostate size, anatomy, and prostate width. Cystoscopy is also performed routinely to rule out any bladder pathology and verify the distance from the bladder neck to verumontanum. The prostate length and width are of particular importance because the length will determine the number of levels at which needle deployment will be required. Prostate of 3 cm or less will be treated at two different zone levels. A length of 3 to 4 cm will require three levels of treatment. Prostates larger than 4 cm will require four zones of treatment. The length into the prostate to which the needles are deployed is based on the prostate width.

Intraoperative. The patient is positioned in the dorsal lithotomy position on a table. A grounding pad is applied to the patient's back in the lumbar area or over the sacrum. The anesthesia of choice is then given. The viscous lidocaine is given per meatus, with a penile clamp left in place to keep the lidocaine in the urethra for 10 minutes. If a periprostatic block is elected, then this is done similarly to the block for a prostate biopsy. The specialized cystoscope is placed per urethra under direct vision. The needles are deployed using controls at the catheter handle base and are able to be rotated 180 degrees to engage the prostate lobes based on these controls. The length of the Teflon shield on the needles should be adjusted so that the prostatic urothelium is spared from any treatment effects (usually 4 to 6 mm). The scope often needs to be pressed into the lobe for the needles to "grab" and keep the catheter from being pushed away from the lobe as the needles are advanced. Needles are deployed directly laterally into the lobes (at the 8 to 10 o'clock position and the 2 to 4 o'clock position).

Once deployed, the needles are placed through the urethral mucosa into the prostatic parenchyma. Once the ideal needle location has been verified and the Teflon sheaths have been advanced to protect the urothelium, the generator is activated. Thermocouples monitor the urethral and needle-tip temperature. The energy is slowly increased until the tissue temperature is reached. The needle tips are more than 6 mm from the prostatic capsule to ensure that no damage to structures outside the capsule occurs. The needle tips are then heated to at least 100°C. It takes only 20 to 30 seconds to reach the treatment temperature, and once it has been achieved the area is treated for 2 to 3 minutes. The delivered energy is adjusted by the software to maintain the temperature.

The needles treat a discrete area around and between the tips, creating an area of coagulative necrosis. For treatment of the entire gland, multiple planes in each gland must be treated. The number of zones and planes required for treatment is dependent on prostate size and shape (Fig. 105-14). In general, the needles are first deployed in a plane 1 cm below the bladder neck into the parenchyma, with subsequent placements at 1-cm intervals in the prostate and with the last placement 1 cm proximal to the verumontanum. The length to which the needle is deployed into the prostate parenchyma is calculated by the software based on the dimensions of the prostate including the width and other measurements from the preprocedural TRUS. During the treatment, temperatures near the needle tips will rise to 115°C within 20 seconds of generator activation. Temperatures are then maintained at that level for 2 to 3 minutes. This temperature and duration should

Figure 105-14. The treated prostate in transurethral needle ablation. (Courtesy Kevin T. McVary.)

cause the desired local tissue necrosis. The tissue temperature should be monitored throughout the procedure along with the urethral temperature. The machine is automatically equipped to shut down if the urethral temperature increases to a potentially harmful level. Treatment is complete once all of the predetermined areas of the prostate have been treated.

Postoperative. Patients are able to return home after the procedure, and convalescence is rapid. A few days of irritative symptoms are normal and likely minimized because of the minimal effacement of the urethral mucosa. If a urinary catheter is placed, it is maintained for 1 to 3 days based on surgeon preference. Antibiotics can be used for up to 2 weeks, and NSAIDs are continued for 10 days. The empirical antibiotic treatment is to avoid bacterial proliferation that forms an abscess in the cavitated necroses of the post-TUNA prostate (Barmoshe et al, 2006). Most patients are able to return to work in 2 to 3 days.

Outcomes. Whereas TUNA does show improvements in both subjective and objective measures of voiding, the results are less impressive than those found with TURP. Studies using UDS frequently show that patients do not migrate from an obstructed classification. A prohibitive need for re-treatment also attenuates enthusiasm. Comparisons to TURP are found in the literature, but no such comparisons of TUNA to medical treatment exist. Although it may have an overall lower rate of efficacy, the treatment is relatively safe, with few if any major adverse events.

Single-Cohort Studies. There is a consensus that TUNA treatment provides improvements in both subjective and objective measure of voiding, at least in short-term studies. However, there is a surprising lack of long-term data published, with only a handful of reports on patients further than 2 years from procedure. A comprehensive study primarily using an early generation of TUNA devices was completed by Rosario and colleagues in 1997 (Rosario et al, 1997). A total of 71 patients who were all found to have obstruction on pressure-flow studies were enrolled. Patients completed a 5-day voiding diary before the procedure and before each visit. Analysis completed at 12 months found a variety of positive results. Significant improvements were seen in multiple subjective outcome

measures, including AUASS (21.9 to 10.6), QoL score (4.8 to 2.2), number of daytime voids (8.7 to 5.6), and number of nighttime voids (2.7 to 1.7). At 1 year, 45 of the original 71 patients underwent repeat UDS. A statistical but clinically questionable decrease in PdetQmax was noted (97 to 82 cm H₂O). None of the patients were able to move into the “unobstructed” portion of the Abrams-Griffiths nomogram and 78% remained “obstructed.” No significant change in prostate volume or PSA was noted. Only 54% of patients were “completely satisfied” with the treatment. A total of 22 (30.1%) went on to additional treatment with TURP. The study by [Steele and Sleep \(1997\)](#) reported a more impressive decrease at 2 years in PdetQmax (92.4 to 58.9 cm H₂O). Maximum flow increased from 6.6 to 11.2 and AUASS decreased from 22.4 to 9.5. A total of 6 patients from the initial 47 patients required TURP during the study period. The researchers attempted to determine any preprocedural values that predicted failure but were unable to find any significant correlations.

In one of the larger noncomparative studies, [Roehrborn and colleagues \(1998a\)](#) studied 130 patients prospectively. Improvements were once again seen in AUASS (23.7 to 11.9) and Qmax (8.7 to 14.6 mL/sec). Surprisingly, 13.1% of patients reported an improvement in AUASS with either a decrease or no change in their peak urinary flow. Conversely, 4.8% of patients noted an increase in Qmax without an improvement in AUASS. Treatment duration was quick (mean 37.4 minutes). Although no patient required general anesthesia to complete the procedure, 22% reported some degree of pain. Most patients (59.2%) were able to void after the procedure. Of those who did require catheterization, the mean duration was 3.1 days, although 1 patient did require a catheter for 35 days.

In one of the few studies with data beyond 2 years, [Zlotta and colleagues \(2003\)](#) enrolled 188 patients into a multicenter study. At 5 years post-procedure, 121 patients were still available for analysis, with another 10 patients reaching 4 years. Significant improvements were seen in Qmax (40.7%), AUASS (−58.4%), QoL score (−55.1%), and PVR (−31.8%). Patients had a fairly large prostate at baseline—a mean size of 53.9 mL—and, once again, no appreciable change in volume was noted with the procedure. In addition, the PSA did not have any significant change with treatment. Of the 176 patients (2 deaths, 10 lost to follow-up) remaining at final analysis, 23.3% required some form of re-treatment. Of the total cohort, 6.4% received additional medical treatment, 3.7% underwent a second TUNA procedure, and 11.1% underwent unspecified surgery.

In one of the few studies examining TUNA in patients with AUR, 20 patients were included. Inclusion criteria included good detrusor function on UDS. In all patients, a trial of void after initial catheterization had also failed. Although all patients remained obstructed by Schafer coefficient after procedure, 17 of the 20 were able to spontaneously void. Five patients later progressed to receiving TURP for symptoms ([Millard et al, 1996](#)). In their review, [Bouza and colleagues \(2006\)](#) analyzed the available data and found that TUNA could reliably reduce symptom scores and QoL values by 50% to 60% compared with preprocedural values. They concluded this improvement was maintained over time, with a downward trend noted after 3 years. According to objective parameters, improvements were more modest but still statistically significant. A 30% to 35% improvement over baseline values was noted in objective measures such as Qmax, with even more poor outcomes on measures obtained from UDS. Of studies assessing patients with acute or chronic AUR, 70% of patients could spontaneously void within the first few weeks after the procedure.

Comparative Studies. Very few studies comparing TUNA with other treatments exist, and of these comparative studies a randomized design was used only in a minority. Although most studies report the standard subjective and objective measure of voiding, complications are irregularly reported. Follow-up beyond 3 years is rare in any type of study, and conclusions regarding long-term durability of this procedure should be made with caution.

Transurethral Needle Ablation versus Other Minimally Invasive Surgical Techniques. In a nonrandomized treatment protocol comparing patients selecting TUNA, TUMT, or high-intensity focused ultrasound (HIFU) for treatment of BPH, discouraging results were found with regard to MIST treatments ([Ohigashi et al, 2007](#)). Although statistical decreases were seen in all three MIST treatments with regard to AUASS at 6 months after treatment, with HIFU (52%) performing better than TUNA (45%) or TUMT (38%), all three treatments no longer had statistically significant improvements at 24 months. Although a large number of patients were lost to follow-up, re-treatment rates were surprisingly high, with 34% of TUMT, 36% of TUNA, and 58% of HIFU patients requiring re-treatment by 3 years. At 5 years, re-treatment rates ranged from 54% to 68% for the groups. In an interesting analysis, the researchers found that an initial Qmax of less than 10 mL/sec and an AUASS greater than 19 were risk factors for re-treatment. This is suggestive that patients with more severe metrics of BOO may be better suited to a different form of treatment. Although data were accumulated only for 3 months post-treatment in their non-randomized trial, [Arai and colleagues \(2000\)](#) found that patients who had undergone TUNA rated their satisfaction with the procedure more highly than those having undergone TUMT. A few studies have compared TUNA to TUVF ([Schatz et al, 1997, 2000; Minardi et al, 2004](#)). The analysis of these outcomes reports that TUVF has a higher risk of adverse events and more significant improvements in subjective and objective voiding outcomes ([Bouza et al, 2006](#)).

Transurethral Needle Ablation versus Transurethral Resection of the Prostate. TUNA was rigorously compared with TURP in an RCT that had data reported at multiple time points. The first installment occurred at 1 year post-randomization and showed that both procedures were efficacious but with superiority in the TURP cohort ([Bruskewitz et al, 1998](#)). A significant decrease was seen in AUASS in both arms at 1 year, with TURP (64% decrease) having a statistical advantage compared with TUNA (55% decrease). Measured prostate volume actually increased in the TUNA group (+2.4%), whereas the TURP group had a 17% reduction ($P = .014$). Peak urinary flow also underwent a more significant improvement in the TURP group (147.6%) compared with TUNA (72.4%), although both groups improved compared with their respective baselines. Longer hospital stay was noted in the TURP group because all patients in the TUNA group went home the day of the procedure. The second installment focused more primarily on UDS changes noted between the treatment arms ([Roehrborn et al, 1999](#)). Changes in the Abrahms-Griffith number and detrusor pressure at peak flow were superior in the TURP group. When comparing UDS changes with symptom improvements, the researchers were not able to predict which preprocedural UDS findings could predict postprocedural subjective success. The final publication from this series occurred after 5 years post-treatment ([Hill et al, 2004](#)). Cautious conclusions should be drawn from these results because at least half of the initial cohort did not provide data at the 5-year mark and in some categories only 20% of the initial cohort was analyzed. Both treatments were found to be effective for BPH, but TURP was superior in almost all metrics. AUASS improvements were more profound from years 1 to 4 for TURP. Peak flow was better at all analyzed time points in the TURP group compared with TUNA. TUNA did have a lower rate of adverse events but a higher need for re-treatment (13.8%) compared with 1.8% in TURP group. Another RCT by [Cimentepe and colleagues \(2003\)](#) had overall results that were more favorable for TUNA, but still not exceeding TURP. They reported no postoperative complications in the TUNA group other than a 7% risk of re-treatment over 18 months.

A meta-analysis of RCTs ([Bouza et al, 2006](#)) concluded that TUNA and TURP were fairly equivalent in results at 3 months, with TURP providing superior results after that point. Results for symptom score were improved by a factor of 1.3 at 1 year and 1.49 at 3 years. QoL score had less of a disparity, with a factor difference in results of 1.14 at 1 year and 1.34 at 3 years. Maximum flow of the TURP group was at least double the improvement seen in TUNA throughout the entire analysis.

Complications. The excellent systematic review and meta-analysis by Bouza and colleagues (2006) analyzed the total complication rates of both open and comparative trials. The researchers found that TUNA had a much higher rate of secondary procedures (OR 7.4) compared with TURP but was safer with a lower rate of complications (OR 0.14). They noted that differences were particularly notable in risk of sexual disorders and postoperative bleeding.

Intraoperative and Perioperative. In the study by Steele and Sleep (1997) a mild post-procedural hematuria was seen in all 47 patients. At 1 month postprocedure, 8% continued to have some degree of irritative voiding symptoms. Pain during the procedure is a fairly common finding, reported in 22% of patients in one series (Roehrborn et al, 1998a).

Postoperative. In the previously discussed comprehensive study by Rosario and colleagues (1997), patients were routinely sent home with catheters after initial problems with postprocedure retention. Likely as a result of this, they had a high rate of UTI (14%). Only 5.8% of patients reported any sexual dysfunction, although the rigor with which this was investigated in the individual trials is suspect. Dysuria was noted in 7% of patients in the review, whereas other studies have reported the incidence of this to be as high as 25% (Ramon et al, 1997). Perineal pain both during and after procedure is a common finding; 50% of patients in one study had pain lasting 1 to 2 weeks, and 23% used pain medication for control of this pain (Daehlin et al, 2002). From the comparative trials, Bruskewitz and colleagues (1998) noted a 12.7% incidence of ED in the TURP group. No TUNA patients reported ED. A decrease in ejaculation was noted in the TURP group 54% of the time, and only 13% of TUNA patients noted the same complaint. At final analysis of this cohort (Hill et al, 2004), 41% of the TURP group reported retrograde ejaculation but no TUNA patients reported this. Prolonged catheterization is unlikely because 90% to 95% of patients have been shown to be catheter free within 1 week of treatment (Chapple et al, 1999).

Conclusion. The role of TUNA in the continuum of BPH treatments is difficult to ascertain owing to the insufficient evidence and a lack of high-quality studies with significant long-term data. Although TUNA statistically improves symptoms, the results with regard to QoL score and urinary flow rates are not as impressive as with TURP. The reduction in prostate volume is negligible because the cavitated areas are putatively replaced with scar, leading to minimal significant change in overall prostate volume. A large initial volume of research was generated, but little has been published in the last few years. Likely this technology is headed toward a minimal role as more durable and impressive options continue to evolve. Although overall the procedure is very safe, it is a less attractive option than other MISTs.

Transurethral Incision of the Prostate

Overview and Concept. A dynamic role of peripheral condensation of the prostatic stroma acting as a capsule leading to BPH-associated LUTS has been proposed (Hutch and Rambo, 1970; Ohnishi, 1986). The alleviation of symptoms seen in patients with BPH treated with α -blockade also supports this capsular contraction or prostatic hypertonicity leading to symptoms. Clearly, capsular constriction could further exacerbate the symptoms derived from an already hyperplastic prostate. The practice of incising the prostate or bladder neck for reduction in voiding symptoms has been verified as early as reports dating back to the 1800s. In their review, Hedlund and Ek (1985) credit Guthrie in 1834 with the first disruption of the bladder neck as a treatment.

TUIP is an operative approach to disrupt the prostatic capsule to alleviate voiding symptoms. This procedure can be considered in many with small prostates (<30 g), although surgeons have tried this in larger glands. In general, a unilateral or bilateral incision is made through the bladder neck and can be extended all the way distally to the verumontanum. This incision is usually made posterolaterally (in the region of the 5 and 7 o'clock positions). The ideal patient for this procedure is a young man with a small

prostate who is concerned about either a loss of ejaculation or future fertility. This procedure has a lower risk of retrograde ejaculation (particularly if only done unilaterally) than other BPH treatment options. However, if retrograde ejaculation is truly being avoided, authors have avoided bladder neck and complete capsular incision (Orandi, 1987).

Technique. The most critical part of the preoperative care before TUIP is correct patient selection. Patients with large glands or significant symptoms are unlikely to achieve significant benefit and will require additional treatment. Many studies exclude patients with a median lobe from the procedure, and this should be considered as a potential contraindication. However, other authors have found that the presence of a median lobe is not a contraindication and opine that with incision of the prostate the median lobe will often become atrophic (Orandi, 1985).

The technique itself is fairly simple and technically straightforward. A cold knife, hot knife, resectoscope with a thin loop or even an end-firing holmium laser can be used to complete the procedure. The incision should be started distal to the ureteral orifice. The incision is carried through the bladder neck into the prostate, ending before the verumontanum. The depth of incision should visualize the surgical capsule at a minimum, although more aggressive surgeons may prefer to see periprostatic fat as they incise through the capsule. Hemostasis should be achieved, but significant bleeding should not be encountered (Fig. 105-15). The patient can have the catheter removed and can be discharged to home quickly after surgery (day of surgery or the next day). Convalescence should be rapid with few or no postoperative irritative symptoms.

Figure 105-15. Transurethral incision of the prostate. The incision is started at the ureteral orifice and carried through the bladder neck up to the verumontanum. This procedure is done bilaterally. (From Mebust WK. A review of TURP complications and the National Cooperative Study, lesson 24, volume VIII. AUA Update Series 1989: 189–90.)

Outcomes

Single-Cohort Studies. Compared with other BPH treatments, TUIP has generated less significant and rigorous research. Only a few large series exist, and they are primarily focused on few authors. In a rigorous study by [Sirls and colleagues \(1993\)](#), a small group of patients were rigorously evaluated with both subjective and objective measures to evaluate the procedure. UDS was routinely performed along with interviews and questionnaires in 41 patients. Data were reported only if patients were followed for a minimum of 12 months. Significant changes were seen in mean peak urinary flow (increased from 10 to 15 mL/sec) and Madsen-Iversen symptom scores (decreased from 12.5 to 6.9). The mean detrusor pressure at maximum flow decreased from 85 to 44 cm H₂O, which was significant statistically but left many patients remaining in the obstructed (29%) or equivocal (43%) classification by the Abrams-Griffiths nomogram. Additional subjective information was obtained by interview. Although no objective questionnaire was used to evaluate sexual function, only 11% of patients reported new retrograde ejaculation. In addition, only 67% of patients reported being overall satisfied with the procedure. In the large series published by [Orandi \(1985\)](#), 646 patients over a 15-year period were assessed. Although not randomized, many patients during that time underwent TURP, and some matching of results was attempted.

Comparative Studies

Transurethral Incision of the Prostate versus Transurethral Resection of the Prostate. The trials comparing TUIP and TURP are of generally poor methodologic quality, with nonuniformity prohibiting any large meta-analysis. Specifics on randomization are most notably missing. In addition, these trials sample a fairly homogeneous group of patients with small prostates. In a randomized study, [Jahson and colleagues \(1998\)](#) evaluated patient prostate volume primarily with DRE (TRUS in some circumstances). In those evaluated by TRUS the average prostate volume was less than 27 g in both groups. The findings are notable in that TURP took longer than TUIP and had a larger estimated blood loss but did provide a larger improvement in postoperative Q_{max}. Ten patients in the TUIP group required reoperation compared with only 3 in the TURP group ($P = .039$).

Another randomized study by [Tkocz and Prajsner \(2002\)](#) included only patients with a prostate volume less than 30 g by TRUS. The age range of included patients was 51 to 78 and assessment was made at 24 months. Whereas both groups had statistical improvements in AUASS, PdetQ_{max}, and Q_{max}, there was no significant difference between groups in these metrics. Retrograde ejaculation was seen in only 12% of the TUIP group compared with 32% of the TURP group, although it was unclear if this was a statistically significant difference.

The largest randomized series was published by [Soonawalla and Pardanani \(1992\)](#). This series excluded patients with glands larger than 30 g. Patients were randomized to either TURP ($n = 110$) or TUIP ($n = 110$); the TUIP group did have a small volume of prostate resected for histopathologic examination. A surprising number of patients (38 of 110) undergoing TURP received a blood transfusion. Peak flow rates were increased in both the TURP (157%) and TUIP (145%) groups.

A fairly recent analysis of randomized trials involving TUIP was published by [Lourenco and colleagues \(2010\)](#). They concluded that the available randomized trials were of “poor to moderate quality” and that in many comparisons only a few trials could be included because some trials did not report methods or results comprehensively enough. TURP had a more significant improvement in flow rates, but conclusions on changes in symptom scores could not be drawn from the data.

Complications

Intraoperative and Perioperative. Hemorrhage should be controlled quickly, although significant bleeding and transfusion are rare. If capsular perforation occurs (either intentionally as part of the procedure or because of an overly zealous incision), in general it can be treated with prolonged postoperative catheterization. In the series by [Orandi \(1985\)](#), 11% of patients had temporary urinary retention after TUIP. Significant hemorrhage was rare, with only

0.9% of patients requiring transfusion. The previously discussed analysis of RCTs ([Lourenco et al, 2010](#)) more confidently reported morbidity data. A higher rate of blood transfusion was found in TURP but was fueled by two studies with abnormally high rates of 35% ([Soonawalla and Pardanani, 1992](#)) and 80% ([Nielsen, 1988](#)).

Postoperative. Retrograde ejaculation is less of a concern with TUIP than with other forms of BPH treatment. Reported rates of retrograde ejaculation range from 0% to 37% but are likely to be toward the lower end of this range. The incidence of this complication is less likely with one incision ([Turner-Warwick, 1979](#)) but other reports came to the conclusion that two incisions did not increase the risk ([Hedlund and Ek, 1985](#)). When compared with TURP, TUIP had a lower risk of retrograde ejaculation (RR 0.54, $P < .001$) but a higher risk of reoperation (RR 2.40, $P < .01$). The risk of ED with either treatment was not different. In addition, the researchers found no difference between treatments with respect to urinary retention, urinary infection, stricture, or incontinence ([Lourenco et al, 2010](#)). In the [Orandi \(1987\)](#) series, 2.9% of patients developed urethral stricture, and a total of 9.6% required repeat prostatic surgery. In less than 1% of patients were complications of incontinence or bladder neck contracture encountered.

Summary. TUIP offers reasonable results in correctly selected patients. It does appear to have a lower risk of retrograde ejaculation compared with other treatment options, particularly TURP. The operation is of short duration and a minimal hospital stay is required. This treatment should be discouraged in a patient with a larger prostate gland but may be of benefit in patients particularly concerned about retrograde ejaculation.

KEY POINTS: NONLASER OPTIONS

- M-TURP is still an important treatment for LUTS and BPH but will continue to progress to B-TURP owing to the multiple improvements in the safety profile.
- MIST treatments such as TUNA and TUMT have been plagued by a high need for re-treatment and likely fill a role between medical management and more invasive and effective treatments for LUTS and BPH.
- TUIP is a reasonable treatment option in the carefully selected patient.

Laser Treatments

Laser treatment of BPH has been an increasingly common choice for urologist and patients. Over the last decade, laser technology has become more refined, leading to improved treatments and outcomes. The term *laser* was derived from the acronym for “light amplification by stimulated emission of radiation.” **Laser prostate treatments rely on the prostate interacting with the light energy and converting it to local thermal energy.** The volume of tissue that is heated by the laser depends on multiple variables including light scatter, reflection, and, most important, absorption. Initial laser technologies relied on tissue coagulation and were eventually abandoned in favor of lasers with a preference for vaporization. **The temperature to which the tissue is heated determines whether the tissue is vaporized or coagulated.** Below the vaporization temperature, the tissue proteins are denatured, leading to coagulative necrosis with delayed tissue death and sloughing. Vaporization occurs when the tissue is heated above the vaporization (boiling) temperature, which leads to intracellular water vaporization and quick tissue destruction.

The amount of tissue that is heated beyond a target temperature during laser treatment of the prostate is based on characteristics of the laser and tissue. Laser characteristics include the irradiation time and power along with delivery characteristics such as power intensity, beam angle, and spread. Tissue variables such as carbonization and light scatter affect tissue heating also and response to the applied energy. An appeal of the laser technologies is the ability to

allow for ambulatory or outpatient surgery or to mimic a more invasive treatment option with a minimally invasive approach (e.g., holmium enucleation replacing OP).

Several characteristics of lasers are discussed briefly here. The wavelength of the laser is the distance between the sinusoidal waves of the laser energy and is measured in nanometers. Energy of a laser is measured in joules and is the amount of work or heat that the laser produces. The laser power is measured in watts and is the amount of energy that the laser produces in a certain amount of time.

Laser Safety

The incorporation of laser energy into the operating room has allowed for many new techniques for the treatment of BPH. The ability to destroy tissue is important for prostate treatment, but when used errantly can lead to unintended consequences such as injury of the patient or operating room personnel. In particular, the human eye is at the highest risk for accidental exposure owing to lack of a protective layer (like the epidermis for most of the body).

The portion of the eye that is injured depends on the wavelength used. For lasers with a larger wavelength such as holmium or thulium lasers, the cornea is at greatest risk. The potassium-titanyl-phosphate (KTP), lithium-triborate (LBO), and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers are particularly dangerous because this wavelength is focused on the retina. The lens of the eye focuses this energy on the retina, causing an increased intensity of up to a factor of 100,000 (Donnell, 2014).

The regulation of the operating environment is standardized by the Occupational Safety and Health Administration (OSHA). **Lasers are classified by their inherent wavelength, maximum output power, and risk of damaging the eye or skin.** All the lasers used by urologists are Class 4 lasers (the highest classification) and can cause permanent eye damage from a variety of exposures including indirect beam contact.

The safe use of lasers in surgery should be done as part of a **culture of safety**. Appropriate OSHA-approved signage should be displayed outside the room so that personnel entering the room are aware of the use of lasers. Appropriate laser-rated protective eyewear should be worn by all persons in the operating room (including the patient) and should be accessible to those entering the room. Any windows or other portals for laser light to leave the operating room should be appropriately blocked to prevent the escape of laser light.

The laser technician or surgeon should review the laser before each case to inspect for any visible signs of damage, and all laser operators should have received appropriate training. Your institution likely has a laser safety officer who can be consulted with any questions regarding laser use or safety.

Holmium and Prostate Enucleation

Overview and Concept. The holmium:yttrium-aluminum-garnet (Ho:YAG) laser emits light at 2140 nm but has a pulsed instead of continuous energy emission. This wavelength is strongly absorbed by water (and water-rich tissues) and has an absorption length of 0.4 mm with excellent hemostatic properties (Kuntz, 2006). The light is easily transmitted along flexible quartz fibers and creates a high-energy density that leads to vaporization with a superficial coagulation zone. The heat from the tissue-fiber interaction is dissipated over a short distance (2 to 3 mm) and causes coagulation of small to medium-sized vessels.

Although this laser has many uses in urology, in general it is now used to precisely incise tissue when used for BPH treatment. Historically, the holmium laser was used also for holmium laser ablation of the prostate (HoLAP), but its hemostatic properties were found wanting when compared with other contemporary laser technologies. **Primarily it is now used to enucleate the prostate in a procedure named holmium laser enucleation of the prostate (HoLEP).** This procedure allows the surgeon to follow anatomic planes to enucleate entire lobes of the prostate. In general, these lobes are then pushed into the prostate with subsequent morcellation.

Holmium laser resection of the prostate (HoLRP) was the precursor procedure to HoLEP. In HoLRP, large sections of the prostate were cut away and pushed into the bladder for later retrieval. **However, with the incorporation of morcellation, the pieces resected could be larger (now entire lobes), and HoLRP fell out of favor for the more efficient HoLEP.** Laser enucleation represents the endoscopic response to open simple prostatectomy and is the most technically advanced for laser prostate surgery. Many reviews and meta-analyses of HoLEP make this the most rigorously analyzed laser technique (Gravas et al, 2011).

Although it is a treatment with excellent results, a difficult and exaggerated learning curve has consistently been seen in adopters of this technique. The enucleation of lobes is not without possible complication, but the morcellator requirement can lead to significant injury to the urinary bladder with catastrophic complications (bladder fibrosis, cystectomy, and need for urinary diversion).

Technique

Preoperative. This technique is probably not necessary for small glands (with many alternatives available) and may be more suitable for patients with a larger gland who would previously have undergone OP. Crossmatching of blood may not be necessary as a routine precaution for this procedure, but the urologist may be well advised to consider a preoperative type and screen for blood products. Antibiotics should be administered as described earlier for TURP. In general, HoLEP is done in a hospital (or outpatient surgery center) using regional or general anesthesia. Patients should be counseled that an overnight stay is expected, with catheter removal the next day.

Intraoperative. Both HoLRP and current HoLEP technology use the Ho:YAG laser generator. An end-firing 550-micron fiber is delivered through a continuous-flow laser resectoscope (usually 26 Fr in size). The laser resectoscope has a modification in which the inner sheath contains a fiber guide to stabilize and prevent fiber movement while in use. A 6-Fr open-ended catheter may also be used as a fiber guide when placed through the sheath. An offset lens of 30 degrees is used along with normal saline irrigation.

The HoLEP technique was initially described by the group from New Zealand led by Gilling (Fraundorfer and Gilling, 1998). The use of the morcellator modified the technique from the HoLRP to the HoLEP. Initially, the size of the pieces that could be removed from the prostate was limited to a size that was small enough to be retrieved through the modified resectoscope. With the addition of morcellation, larger pieces were able to be fragmented and removed, making enucleation possible. These whole prostate lobes were moved into the bladder after enucleation, with morcellation then commencing after the entire enucleation was complete.

An 80- or 100-W generator is used. In general, the power settings are 2.0 J at 50 Hz, giving the surgeon a total of 100 W. **The procedure begins with a bladder neck incision at the 5 and 7 o'clock positions.** These incisions are carried down to the surgical capsule, which is identified by its reflective fibers running longitudinally. This is an important distinction because the landmark will mark the depth for the remainder of the procedure. **The incisions are lengthened distally to just proximal to the verumontanum.** Incisions are widened laterally by following the surgical capsule to undermine the lateral lobes. This allows for improved visualization with a larger channel of irrigation influx to the bladder and sets up later steps in the case.

A transversely oriented incision is made between the distal aspects of the previously extended bladder neck incisions. This begins the undermining of the median lobe in a retrograde fashion. **The surgical capsule is followed as the median lobe is lifted off the capsule.** The beak of the scope may be used to retract the median lobe to improve visualization. This step is complete once the median lobe has been enucleated and advanced into the bladder. Care should be taken to not undermine the bladder during the latter portion of this step. **The incisions made at the distal aspects of the lateral lobes are now developed to enucleate the lateral lobes.** These incisions are developed laterally up the walls, once again following the surgical capsule. Initially this is

done circumferentially at the apex of the prostate and then carried proximally toward the bladder neck, separating the adenoma from the capsule. An incision at the 12 o'clock position is then made down to the capsule. The surgical capsule is now followed from both the inferior and 12 o'clock position until the entire lobe is free and can be moved into the bladder. The procedure is repeated on the other side and hemostasis is achieved using a defocused laser beam to coagulate any bleeding.

Morcellation is then used to remove the large adenoma pieces from the bladder; the morcellator digests these large pieces down to more manageable strips of tissue. A dedicated scope or nephroscope with a 5-mm working channel is used. The morcellator itself has two blades within a long hollow inner lumen. The bladder is distended to keep the bladder wall away from the morcellator's moving pieces. A foot-operated variable suction is applied to the morcellator to draw the adenoma pieces toward the morcellator. Once the pieces are engaged, the morcellator's guillotine action slices off fragments of tissue. These smaller fragments are able to be suctioned through the lumen of the morcellator. A unique complication of the morcellator is bladder injury, and the operator should be careful to stop suctioning if the blade engages the bladder mucosa. Small, residual fragments may be removed with the flow of irrigation through a resectoscope sheath or with a large-bore syringe.

An alternate technique of lobe fragmentation or "mushroom" technique involves leaving the lobes attached at a stalk and then resecting the lobes down into pieces suitable to come through the resectoscope (Hochreiter et al, 2002). A urethral catheter is then carefully placed after all the fragments have been removed. Of course, this technique allows for preservation of the tissue for histologic examination, and the morcellated pieces should be sent to the pathologist for examination. Additional hybrid holmium resection and enucleation techniques have been described that improve the learning curve and have decreased complication rates compared with traditional HoLEP (Helfand et al, 2010).

Postoperative. A minimum of an overnight hospital stay is generally accepted, and patients can expect to be discharged on the first postoperative day. In the absence of a definitive capsular perforation, the catheter can be removed first thing in the morning. If a large perforation has occurred, the catheter should be left for a few days and then removed in the clinic without further repercussions. Whereas most bladder injuries during morcellation are superficial and require no additional treatment, large extraperitoneal or intraperitoneal bladder injuries may require exploration and closure. Unless there is a large degree of extravasation of irrigant from an extraperitoneal injury, these can usually be managed conservatively with extended catheterization.

Outcomes

Single-Cohort Series. Large series of patients appeared quickly. One of the early adopters reported on 552 patients retrospectively in 2005. Elzayat and colleagues (2005b) found a 200% increase in Qmax to complement a 75% improvement in AUASS at 1 year. A short mean catheterization (1.4 days) and hospital stay (1.5 days) were also observed. Authors quickly reported on successful treatment of large glands, customarily removing more than 100 g at surgery (Moody and Lingeman, 2001). The ability to handle such large glands quickly made this a unique endoscopic treatment because most other technologies did not include gland sizes larger than 70 or 80 mL in studies. Studies looking at patients with AUR displayed the effectiveness of the treatment. In a study of patients with a mean volume of 670 mL urine drained at initial catheter placement, only 1.75% of patients were unable to void after surgery (Elzayat et al, 2005a). In another study of patients with urinary retention, all patients were able to void after surgery (Peterson et al, 2005).

Longer-term data continued to be encouraging. In a review of 118 cases by Elzayat and Elhilali (2007), objective data were available on only 26 patients at 6 years, but mean flow increased from 6.3 to 16.2 mL/sec and mean AUASS decreased from 17.3 to 5.6 ($P < .0001$ for both). The researchers observed that 8% of their first 50 patients required re-treatment but only 1.5% of the later 68

patients required re-treatment, hinting that a significant learning curve may be expected. Enucleated tissue weight and total energy used were increased in the latter group, possibly explaining the lower re-treatment needs. Krambeck and colleagues (2010a) reported on their data from 1065 HoLEP patients. Although the researchers had a mean follow-up of less than a year at 287 days (range 6 to 3571 days), they observed an increasing maximum flow and a decreasing AUASS when stratifying patients by time from procedure. This further solidified the long-term efficacy of the procedure.

The popularity of HoLEP has been hampered by concerns about a steep learning curve. This was evident in the analysis of the first 125 patients undergoing the procedure performed by a self-taught surgeon (Placer et al, 2009). In skilled hands, HoLEP can treat glands over 175 g with a reported outcome equivalent to OP with a low morbidity (Krambeck et al, 2010b), but it has been estimated that a self-taught trainee must perform at least 20 procedures on moderate-sized glands before being able to reliably reproduce high-quality results (El-Hakim and Elhilali, 2002).

An advantage of the HoLEP technique is that it appears that prostate size does not influence efficacy in a surgeon with experience in this technique. When researchers broke down prostate size into three groups with increasing size, they found that whereas mean resected tissue weight increased among groups, the groups all had immediate and profound changes in AUASS, flow rates, and residual volume. Complication rates were roughly equivalent, with only a slight increase in bleeding noted with increasing prostate size (Kuntz et al, 2004b).

Comparative Series

Holmium Laser Enucleation of the Prostate versus Transurethral Resection of the Prostate. A large RCT looking at HoLEP vs. M-TURP was initially composed of 200 urodynamically obstructed patients who were randomized to HoLEP or M-TURP. Results were released in two reports. Prostate volumes were measured by TRUS and were approximately 50 g in both groups, and patients had high PVRs (>200 mL in both groups). Follow-up was available out to 36 months; operative and 12-month statistics were published in the initial report. The researchers reported a significant decrease in hemoglobin (1.3 vs. 1.8 g/dL), catheterization time (27.6 vs. 43.4 hours), and hospital stay (53.3 vs. 85.8 hours) in an initial report (Kuntz et al, 2004a). Operative time was longer in the HoLEP group (94.6 vs. 73.8 minutes). Peak flow rates improved from 4.9 to 23.1 in the HoLEP group, and in the TURP group improved from 5.9 to 25.5, at 12 months without differences seen between groups. Residual volume in the HoLEP group was superior compared with TURP (4.8 vs. 16.7 mL at 6 months and 5.3 vs. 26.6 mL at 12 months), although with such low volumes that this is likely not clinically significant. AUASSs were in the low 20s in both groups preoperatively and 4.3 (HoLEP) and 5.5 (TURP) at 1 month. At 36-month assessment, PVR continued to be significantly lower in the HoLEP group (202 mL vs. 8.4 mL). The statistical difference between AUASSs was no longer present, but both groups had a very low score (2.7 for HoLEP, 3.3 for TURP). Flow rates were not different between groups and were over 27 mL/sec in both groups (Ahyai et al, 2007). Other RCTs have verified the increased operative time and decreased catheterization and hospital time (Tan et al, 2003; Montorsi et al, 2004).

The 7-year follow-up of Gilling's data was recently published (Gilling et al, 2012). Thirty-one of the initial 61 patients were included. Data from the initial operation were reviewed and are in agreement with the increased operating room time and prostate tissue weight removal. Catheterization (17.7 vs. 44.9 hours) and hospital time (27.6 vs. 49.9 hours) were once again lower for HoLEP vs. TURP. The researchers concluded that HoLEP is at least equivalent to TURP with regard to durability. In their data, 3 of the TURP patients required additional intervention for BPH (compared with none in the HoLEP group).

Multiple meta-analyses have been performed looking at RCTs of HoLEP vs. TURP. Lourenco and colleagues (2008) found increased rates of Qmax for HoLEP compared with TURP (weighted mean difference of 1.48 mL/sec). Symptom scores trended toward an

advantage for HoLEP but did not quite meet statistical significance. Lourenco and colleagues and the researchers who performed another meta-analysis (Tan et al, 2007) found shorter catheter and hospital times. With different RCTs included, the analysis of flow rates did not meet statistical significance in the latter review.

The most convincing data for the usefulness of HoLEP was published in the meta-analysis of RCTs by Ahyai and colleagues (2010). They concluded that operating room time was indeed increased, but that owing to the large weight of adenoma removed in studies, HoLEP and TURP have similar time efficiency (weight of adenoma removed versus operating room time). Catheter time was also found to be shorter in the HoLEP group. It is most interesting to note that statistical superiority in support of HoLEP was seen with regard to change in AUASS and Qmax. The authors concluded that HoLEP was the only endoscopic procedure that has shown superiority to TURP. For longer-term data, Cornu and colleagues (2014) analyzed results after 3 to 8 years post-procedure. Although data could be reliably drawn from only the two studies in the analysis, results still appear to favor HoLEP.

Holmium Laser Enucleation of the Prostate versus Open Prostatectomy. HoLEP is so effective in treating BPH that it has even been compared favorably with OP. Two randomized trials looked at the use of HoLEP versus OP in large glands. A study wherein all glands were greater than 70 g (mean size of 113 g in the HoLEP and 124 g in the OP groups) had a standard randomization (Naspro et al, 2006). The authors found decreases in time to catheter removal (4.1 vs. 1.5 days), patient in-hospital time (5.4 vs. 2.7 days), and risk of transfusion of blood (seven vs. two patients) for HoLEP. Operative time was shorter in the OP group (72 vs. 58 minutes), and this group had a larger weight of adenoma removed (87.9 vs. 59.3 g). Patients underwent repeat urodynamic assessment at 12 months and had uroflow and AUASS available out to 24 months. Comparable urodynamic improvements were seen in both OP and HoLEP groups. Qmax improved from 7.8 mL/sec in the HoLEP group to 26.6 mL/sec initially and 19.2 mL/sec at 2 years. The OP group initially voided at 8.3 mL/sec, which improved to 24.3 mL/sec at 1 month and 20.1 mL/sec at 2 years. **Between groups, there was no statistical difference in voiding rates at any time.** AUASS was also assessed for patients in both groups. Initial scores were high in both groups (20.11 in HoLEP and 21.6 in OP group), decreased to 6.9 and 4.7 at 1 month, and were 7.9 and 8.1 at 2 years in the HoLEP and OP groups, respectively. **There was no statistical difference at any time point in the AUASS between groups.** Five-year follow-up was available in another study looking at patients all with glands over 100 g (Kuntz et al, 2008). Once again, large changes were seen in AUASS with treatment. The HoLEP group AUASS decreased from 22.1 preoperatively to 2.3 at 1 year, with the OP group having a drop from 21.0 to 2.3; difference between groups was not statistically significant. Operative time was longer, but no patients received transfusion in the HoLEP group (compared with 13% in the OP group) and HoLEP patients had shorter lengths of hospitalization and catheterization. At 5 years, AUASS was 3 in both groups, demonstrating excellent durability for both of these treatment options. PVR and Qmax were not different between treatment groups. Bladder neck contractures and urethral strictures were noted in both groups, but there was no statistical difference in likelihood of these delayed complications or difference in requirements for intervention for complications.

Holmium Laser Enucleation of the Prostate in the Anticoagulated Patient. Tyson and Lerner (2009) looked at 13 patients continuing warfarin and 25 patients continuing aspirin during HoLEP compared with 39 controls. Groups were equivalent; there were no statistically significant differences in outcomes between the groups, and no patient received transfusion in the study. However, the average INR was 1.5 in the group on warfarin, with only two patients having an international normalized ratio (INR) above 2 in the study. Another study (Hochreiter et al, 2002) looking only at patients on warfarin found an average INR in the therapeutic range at 2.7 (range 2.1 to 3.9). These researchers examined 19 patients and compared with 137 controls using their "mushroom technique." No patients required blood transfusion,

but 2 patients in the warfarin group had clot retention that was managed conservatively with irrigation. Of patients in the therapeutic range of warfarin, only 2 patients even had hematuria postoperatively.

Complications

Intraoperative and Perioperative. Although the use of the morcellator has led to decreased operative times compared with HoLRP (Gilling et al, 1998), it does enable a unique complication in that morcellator-mediated bladder injury can occur. These injuries are usually superficial, but deeper and more significant injury is certainly possible because the morcellator engages tissue indiscriminately. Keeping a reasonable volume of irrigant in the bladder and a bloodless field may help visualization and reduce this risk. Reported ranges of these injuries vary widely, with one study reporting an 18.2% occurrence (Montorsi et al, 2004).

Another unique complication is the possibility of incomplete evacuation of the adenoma leading to postponed morcellation. This is usually caused by a malfunction of the morcellating device or poor hemostasis leading to obscured vision. During either enucleation or morcellation there is the possibility of injury to the ureteral orifice. This outcome has been examined in only a few series. The report of Shah and colleagues (2007) found a 2.1% chance of occurrence, whereas another series (Kuntz et al, 2004b) found that of the four such injuries that occurred, three were in the group with the largest prostates (>80 g).

Capsular perforation typically occurs as the resection is carried along in the plane between the prostate adenoma and the surgical capsule. Although carrying into the adenoma in this area will cause bleeding, an error to the other side will lead to capsular perforation. Many authors classify these perforations into categories including "threatened," "covered," or "free" and use the degree of perforation to guide management. In general, authors have managed complete or "free" capsular perforation with prolonged catheterization (a few days), with no change in management for other types of perforation. The incidence of this complication has been reported to be as high as 9.6% (Shah et al, 2007); another large review placed the incidence lower, at 1.5% (Kuo et al, 2003).

The overall risk of hemorrhage during HoLEP is fairly minimal. A defocused holmium laser beam can be used to control most bleeding, and conversion to another form of transurethral intervention is a rare event. It does appear that the risk of bleeding increases with increasing gland size, although the correlation was fairly weak. (Kuntz et al, 2004b). Bleeding is also well controlled by the hemostatic properties of the holmium laser. Some series have reported a transfusion rate as high as 1.7% after HoLEP (Shah et al, 2007), but data incorporated into the meta-analysis of Lourenco and colleagues (2008) found that HoLEP had a decreased RR of transfusion compared with TURP (RR 0.27).

Postoperative. Urinary urgency and other storage symptoms are a common finding after HoLEP and thought to be caused by the high amount of laser energy applied to the capsule during enucleation (Shah et al, 2007). In attempts to grade the severity of these symptoms, Larner and colleagues (2003) found that most patients characterized the symptoms as mild (defined as causing minimal bother). **Transient urinary incontinence** occurs with some frequency but usually resolves with time. In the study by Shah and colleagues (2007), 10.7% of patients reported initial incontinence; only 0.7% of the cohort maintained this complaint permanently. A similar pattern was seen in another large study in which 4.2% initially reported stress-type incontinence but only 0.5% had this complaint at the last visit before publication (Elzayat et al, 2005b). This condition may be avoided by careful incision at the 12 o'clock position with care to not incise distal to the verumontanum. The depth and length of the required incision may be mistaken by a more novice surgeon (Shah et al, 2007).

The incidence of **bladder neck contracture** is 0% to 3.2% (Shah et al, 2007); it appears more likely to occur in smaller prostates (Kuo et al, 2003). The surgeon may consider a prophylactic bladder neck incision in patients they deem at higher risk for this complication. **Urethral stricture** is a common finding, with studies reporting an incidence as high as 7% (Seki et al, 2003) and a more

recent meta-analysis finding a rate of 4.4% (Ahyai et al, 2010). The large-diameter instruments used during the procedure may predispose to this occurrence. Although the location of the stricture was not frequently reported, one group found this to occur more frequently at the meatus (Seki et al, 2003).

Retrograde ejaculation is a common finding after HoLEP. Two randomized trials found incidence rates of 75% and 78% (Briganti et al, 2006; Wilson et al, 2006). However, one of these trials found that changes in IIEF domains were minimal (Briganti et al, 2006).

Conclusion. HoLEP is an interesting treatment option overall. Although there are concerns about an exaggerated learning curve, results are comparable if not superior to those of TURP. Patients have a significantly decreased catheterization and hospital times. Whereas the time in the operating room is increased compared with TURP, many studies show equivalent efficiencies in tissue removal, offsetting the increased surgical time. In addition, it appears that re-intervention rates for BPH may be lower. Complication profiles show HoLEP to have a lower rate of transfusion and similar rates of bladder neck contracture and urethral stricture compared with TURP.

Prostate Ablation and Vaporization

Overview and Concept. The KTP- and LBO-labeled lasers are a derivative of the Nd:YAG laser. The 1064-nm wavelength Nd:YAG laser beam is passed through a KTP or LBO crystal that doubles the frequency of the light and decreases the wavelength to the desired 532 nm. **This wavelength is selectively absorbed by hemoglobin, which acts as an intravascular target for the light energy.** The improved energy density compared with the Nd:YAG laser leads to preferential vaporization, with the hemoglobin absorption improving hemostasis because a thin (0.2 mm) layer of coagulation would be created outside the area of vaporization. The laser energy freely moves through irrigating fluid without a loss of power.

The original KTP laser (GreenLight PVP [American Medical Systems]) used a 532-nm wavelength and was available in 80- and 100-W settings. The LBO laser (GreenLight HPS and XPS [American Medical Systems]) also uses a 532-nm wavelength like the KTP. This laser offered higher-energy 120-W (HPS) and 180-W (XPS) settings. This 180-W setting allows for even more efficacy in vaporization and coagulation (Malek et al, 2011). The 180-W fiber (MoXy Fiber [American Medical Systems]) also has improvements including a built-in water cooling system with automatic safety system that protects the fiber from overheating.

Although the Nd:YAG was originally thought to be the ideal laser fiber for treatment of BPH (Anson et al, 1993), the large amount of prostate sloughing that occurred after visual laser ablation of the prostate (VLAP) because of the extreme depth of laser penetration was later found to be undesirable. The delayed bulk prostate sloughing would often lead patients to develop intermittent voiding and urinary retention postoperatively. The failure to sufficiently vaporize tissue was evident in an in vivo canine study (Kabalin et al, 1995).

In general, VLAP used a larger wavelength laser than the currently used KTP or LBO but the technique was similar to the current technique. As the power of the laser improved, the term *ablation* gradually migrated to *vaporization* because of the immediate removal of tissue visualized during surgery as opposed to the delayed sloughing of tissue seen with ablation. An early canine study comparing the Nd:YAG with the KTP laser displayed the advantages of a laser system that favored vaporization over ablation and coagulation. In this small study, **KTP resulted in significant increases in defect size in the prostates, leaving a thin but effective layer of coagulated tissue** (Kuntzman et al, 1996). Unsurprisingly, as the power of the laser has increased, there have been corresponding improvements in the tissue vaporization (Kang et al, 2008; Malek et al, 2011; Rieken et al, 2013).

The advantage of the PVP technology is the combined vaporization and coagulation. While tissue volume is decreased by the

vaporization, coagulation leads to almost instantaneous hemostasis with closure of venous sinuses, reducing absorption of irrigation fluid.

Technique

Preoperative. A standard preoperative workup should be completed for PVP. Routine cystoscopy is not necessary unless there is a particular concern. Concurrent infection should be ruled out and treated before the operation. Many physicians advocate the use of TRUS to determine prostate size because they have a maximum prostate volume at which they will choose another treatment option instead of PVP. The knowledge of gland size also allows the physician to know the rough estimate of operative time to allow appropriate operating room scheduling. **Patients taking anticoagulation can be managed in many different ways before this procedure.** It is our preference to allow patients who are already on antiplatelet medications to continue these throughout the operative period. However, we do prefer that patients requiring ongoing warfarin therapy be bridged to heparin, which is stopped for the procedure.

Intraoperative. The laser fiber is a 600-micron side-firing probe with the energy produced by the fiber at a 70-degree angle to the fiber longitudinal axis. **Vaporization occurs by sweeping the fiber along the prostate parenchyma, sequentially vaporizing layers of the prostate from the inside out.** Vaporization of the prostate is complete when the capsule fibers are visible. **The distance between the laser fiber and prostate tissue (working distance) is important for many reasons and is often difficult to control for the vaporization novice.** A distance too close will lead to possible "contact vaporization" and resulting damage to the laser fiber. A distance too far will lead to inefficient energy use with more tissue coagulation (and a subsequent increase in postoperative storage symptoms). If in tight quarters, such as at the beginning of the case when the lateral lobes may still be in contact, lower power should be used. Tissue buildup on the fiber should be avoided because this leads to fiber degradation and possibly to shortened fiber life and further inefficiencies.

Management of the bladder neck is an important part of the procedure and is usually the first step. In general, we prefer to use a lower power setting (80 W) in this area. **The ureteral orifices should clearly be identified before beginning treatment of the bladder neck.** A single midline incision of the prostate or two incisions at the 5 and 7 o'clock positions allow for the bladder neck to spring open and level the prostate fossa with the trigone of the bladder. After this is complete, the laser fiber should be pointed in a medial or lateral direction to allow for visualization of the vaporization, which is often lost with vaporization straight posteriorly. In addition, any potential injury to the ureteral orifices should be minimized by orienting the laser beam laterally. Aggressive coagulation at the bladder neck should be avoided. We customarily do not vaporize the anterior portion of the prostate in this area to leave a rim of intact urothelium to prevent circumferential vaporization and possible bladder neck contracture. In patients concerned about retrograde ejaculation, incision of the bladder neck fibers should be avoided.

Movement of the fiber into position for vaporization should be done preferentially with a minimization of cystoscopic motion. A continuous, even motion of the sweeping action of the fiber is vital to minimize large and irregular crater formation in the prostate. Bleeding in a recessed portion of the prostate has the potential to be a significant problem because the vessels are unable to be visualized. The angle and time of the laser fiber sweeps are important factors. If the angle is changed too rapidly, insufficient energy will be transferred, leading to poor vaporization. However, if the laser beam is left on tissue for too long a time (slow sweep), a crater will be formed as the energy accumulates in one area. The sweep angle at which the fiber is turned is also an important factor. It may help the novice to imagine that the laser energy is like hot water on snow. Research from an in vitro study found that the most efficient vaporization occurred when the angle was between 15 and 30 degrees. The depth of coagulation was minimized at 30 degrees of sweep (Ko et al, 2012).

Bleeding is more frequently seen at the prostate apex, median lobe, and bladder neck (particularly at the posterolateral aspects where the blood supply of the prostate enters). If bleeding is not severe, the laser may proceed with caution, focusing on the areas directly adjacent to the bleeding vessel because this may allow for hemostatic control of the feeding areas. If pulsatile, arterial bleeding is recognized, the coagulation mode on the laser may be used. This should once again be used on the area around the bleeding along with the bleeding area itself.

If bleeding is unable to be controlled, a Bugbee electrode may be placed through the working bridge. This allows for the placement of pressure on the vessel to stop continued bleeding (improving visualization) and then controlled coagulation. The surgeon should keep in mind that the irrigating fluid will likely have to be changed to something nonionic. If all else fails, a larger sheath and possibly the resecting loop should be inserted to help control bleeding. Such need is markedly infrequent in experienced hands. When vaporization is complete and hemostasis is verified, the bladder should be examined one more time to ensure there is no erroneous laser damage. A catheter should then be placed and irrigation of the bladder should verify clear irrigant.

Throughout the procedure, the surgeon should be aware of inefficient vaporization. Large bubbles should be visible coming from the tissue throughout vaporization as an indication of efficient energy use. When this is not seen, the laser energy is being used inefficiently and most likely is causing coagulative necrosis or charring of the tissue. When the tissue is charred, the subsequent vaporization will be more challenging, leading to excessive energy use. Unnecessary coagulative necrosis should be avoided because this would lead to more pronounced postoperative dysuria and possible passing of tissue per urethra.

Postoperative. In almost all cases the catheter can be removed the day of or the day after surgery. Bleeding should be minimal in the postoperative period, although patients will customarily pass some tissue with minimal bleeding 7 to 10 days from the surgery date. In cases of minor but continued bleeding, patients can be encouraged to increase fluid intake with careful outpatient follow-up. It is our custom to discharge patients home the day of surgery, with them removing the catheter the next day at home.

Dysuria in the postoperative period is caused by technical inefficiency during the procedure as tissue is being coagulated more than vaporized. The degree of dysuria is correlated with the volume of coagulated tissue (Choi et al, 2008). Patient characteristics that may lead to a risk of dysuria include a large median lobe, previous prostatitis, dense or fibrous prostate tissue, or previous treatments that change prostate tissue characteristics (TUNA, TUMT). In general, sterile pyuria should be noted and can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) if severe. Although dysuria can be a common finding in these patients, the physician should always consider re-evaluation for an unexpected complication such as a tissue flap or retained fiber fragment. Even in the best vaporizations, a layer of coagulated tissue will remain that could potentially lead to a subacute prostatitis and an increased risk of UTI. If a true infection is suspected because of either prolonged dysuria or a positive urinalysis or culture, culture-directed antibiotic therapy should be initiated and culture should be repeated after completed therapy.

Outcomes. The rapid acceptance provided a considerable number of early studies looking at the outcomes of the lower-energy laser fibers. Because the manufacturer continues to update the laser power over time, long-term results have become more difficult to incorporate into practice; frequently a new power level is available as the research from the previous generation is being released. Overall, the PVP technology has been viewed to have a forgiving learning curve with a favorable safety profile.

Single-Cohort Studies. The first pilot study looking at the use of the 80-W KTP laser was published by Hai and Malek (2003). Ten patients were treated and then followed for a year. Significant improvements in AUASS, QoL score, Qmax, and PVR were noted initially with durability to a year. This was quickly followed by a multicenter trial study of 145 patients (Te et al, 2004). Once again,

improvements 12 months after the procedure were noted in AUASS (−82%), QoL score (−77%), Qmax (190%), and PVR (−78%).

The change in urodynamic parameters even with the 80-W laser was encouraging. In urodynamically obstructed patients who underwent PVP, a decrease in Schafer obstruction grade from 3.6 to 1.1 was noted at 12 months ($P < .0001$) with a decrease in PdetQmax from 75.0 to 36.6 cm H₂O (Hamann et al, 2008). The authors also found that the mean number of nighttime (3.5 to 1.2) and daytime (7.2 to 5.7) voids decreased with treatment.

Data became available on the 500 patients treated with the 80-W fiber in 2008 (Ruszat et al, 2008). With a mean follow-up of 30.6 months, the results of patients with 3 years of follow-up showed a mean AUASS of 8.0, QoL score of 1.3, and Qmax of 18.4 mL/sec, proving treatment durability. In patients with 5 years of data (only 5.4% of the cohort), there was not an appreciable difference in these numbers compared with the data at 3 years. The re-treatment rate of the cohort was 6.8%, with a rate of urethral strictures of 3.6% and 4.4% for bladder neck contracture. Dysuria and bladder neck contractures were more common in smaller glands, but larger glands did not lead to a higher risk of re-treatment. In another study evaluating the use of the 80-W laser in large prostates, re-intervention because of residual adenoma was 23% in the larger-gland (>80 mL) group compared with only 10.4% ($P = .09$) in the group with glands smaller than 80 mL (Pfitzenmaier et al, 2008).

As the improved hemostatic qualities of the laser were recognized, challenging patient populations were tested. Patients requiring anticoagulation were able to be safely treated (Sandhu et al, 2005). Although many of the other endoscopic treatments were not rigorously tested on large glands, the improved visualization during vaporization allowed many early adopters to attempt treatment of large glands (>80 g). The International GreenLight Users (IGLU) Group compiled some of the early data on 120-W laser treatment of patients both with large glands and undergoing anticoagulation (Woo et al, 2008). For all the studied patients there were improvements in Qmax, PVR, AUASS, and prostate volume compared with baseline. The use of anticoagulants did not significantly increase complications. Large glands did not alter outcomes beyond the expected larger change in prostate volume. A reduction of 52.5% was seen in larger glands compared with 42.3% in glands smaller than 80 mL ($P < .001$).

Retrospectively reviewed 3-year results of the 120-W HPS reported durability and indicators of response (Cho et al, 2012). Preoperative AUASS was 21.7 and reached a nadir of 11.5 at 6 months but was not statistically higher at 3 years (13.4). Maximum flow followed a similar pattern, improving to 15.7 mL/sec from 8.7 mL/sec at 6 months with a value of 13.9 mL/sec at 3 years. Predictors of response were reported as AUASS greater than 19, with even higher scores being more likely to respond. All voiding diary parameters were predictors under univariate analysis, but only nocturia remained a significant predictor when multivariate analyses were performed. Patients customarily underwent UDS, and the BOO index (BOOI) and bladder contractility index were predictors of a good outcome. Operative time and energy used during the procedure were not predictive. Another case series on the 120-W HPS was published almost concurrently. The authors reported on 75 patients at 36 months and found improvements of 60.2% in AUASS, 80.9% in QoL, 138.7% in Qmax, and 82.6% in PVR compared with baseline. The median prostate volume was reduced by 50.4% (Zang et al, 2012).

In one of the few large studies examining the 180-W XPS, data were collected prospectively from seven European centers accumulating a total of 201 patients (Bachmann et al, 2012). Mean follow-up was 5.8 months. Improvements were seen in AUASS (19.6 to 9.4), QoL score (3.9 to 1.4), Qmax (8.4 to 21.0 mL/sec), and PSA (5.5 to 2.0 ng/dL) at 6 months. These findings were considered analogous with previously published 120-W data by the authors. Impaired visibility because of bleeding was not influenced by active anticoagulation, but capsular perforation, a smaller gland, and preoperative catheterization were risk factors.

Comparative Studies. In one of the first RCTs comparing 80-W PVP with TURP, Bouchier-Hayes and colleagues (2006) compared the results of trainees who had performed between 35 and 325 TURPs but had done at most 5 laser prostatectomies. They exhibited comparable improvements in Qmax (149% for TURP, 167% for PVP) and AUASS (roughly 50% decreases in both groups). This study exhibited the relative ease of performing the procedure and went on to conclude that PVP was 22% cheaper than TURP primarily because of the shorter hospital stay. Another RCT comparing the 80-W PVP and TURP focused on patients with glands larger than 70 g (Horasanli et al, 2008). Operating time favored TURP, whereas time in the hospital and time with catheter favored PVP. Differences in the final AUASS, Qmax, and PVR favored TURP within the follow-up period. Blood transfusion was more common in the TURP group, whereas the PVP group had an increased risk of postoperative retention and need for re-intervention (17.9% in the first year). The summary of these results shows the excellent safety profile but decreased efficacy of the lower-energy PVP (especially in larger glands).

In an RCT comparing the 120-W HPS to TURP, Al-Ansari and colleagues (2010) found dramatic improvements in Qmax, AUASS, and PVR in both groups out to 36 months. TURP did outperform in many metrics (Qmax, AUASS, PVR, mean PSA, mean prostate volume), although the differences were not statistically significant. Although intraoperative complications were significantly fewer in PVP, a strikingly high 93% of patients experienced dysuria or urge and 11% required re-treatment for residual adenoma (compared with only 1.8% of the TURP group, $P = .001$). Mean catheterization and mean hospital stay did favor PVP. Another RCT looking at the HPS versus TURP was completed the following year (Capitán et al, 2011). Once again, similar improvements were seen in Qmax, AUASS, and QoL; however, these improvements appeared to be more rapid in the PVP group. It is interesting to note that the researchers further stratified the AUASS questionnaire and did not find an increase in storage symptoms for the PVP group. Intraoperative, early, and late complications did not differ between groups.

In their review of both 80- and 120-W PVPs in RCTs, Thangasamy and colleagues (2012) consistently found that catheterization and hospital stays were shorter in patients undergoing PVP by 1.91 and 2.13 days, respectively. Operative times were shorter in the TURP cohort by almost 20 minutes, with PVP having a risk ratio of 0.16 for blood transfusion compared with TURP. Other complications were not statistically different. In this group of mixed laser powers, six of the nine studies found no differences in functional outcomes. The one study that favored PVP was an 80-W study that never appeared to reach final publication. The two studies favoring TURP both specifically looked at patients with large prostates (>70 g) and had a laser power of 80 W. In their analysis of 120-W PVP, Cornu and colleagues (2014) found a decrease in catheter time (mean 23 hours) and length of stay in hospital (mean 1.84 days).

Few studies have reliably compared the new XPS and previous HPS systems. In a nonrandomized series of consecutive patients, Ben-Zvi and colleagues (2013) found that mean operating time and mean lasing time were decreased in the XPS group with comparable energy delivery. The significantly different reductions in PSA (54% in HPS vs. 79% in XPS, $P < .01$) show that the XPS surely has a higher efficiency of tissue vaporization, although notable clinical parameters (AUASS, QoL, Qmax, PVR) were not different between groups. Postoperative retention was higher in the HPS group (16% vs. 6%).

Use of Photoselective Vaporization of the Prostate in Anti-Coagulated Patients. A total of 116 men were included (36 on warfarin, 9 on clopidogrel, and 71 on aspirin), and all continued on their medications through the perioperative period while undergoing 80-W PVP. (Ruszat et al, 2007). These groups were compared with 92 controls who were not on anticoagulants or antiplatelet medications. The control group was younger and had a lower ASA class. The average INR was 2.0 (range 1.3 to 2.9), with 14 of the 36 patients on warfarin having an INR of 2 or less. No patients required transfusion, but patients in the study group did have an increased hospital time (3.8 days vs. 2.8) and were more likely to have CBI

for 24 hours (17% vs. 5%). In particular, patients with an INR greater than 2 required CBI postoperatively. Other studies have shown the same risk of transfusion in a group of patients on mixed forms of anticoagulants or antiplatelet medications (Sandhu et al, 2005). An uncontrolled study reporting on 43 patients continuing warfarin during surgery showed no patient requiring transfusion. Two patients did require prolonged catheterization subsequent to bleeding, but 70% of patients were discharged home within 24 hours of surgery (Woo and Hossack, 2011). A Cochrane review that compared laser treatment methods with TURP found an overall reduced risk of transfusion with laser prostatectomy (Hoffman et al, 2004). Based on the aforementioned evidence and our own clinical experience, we routinely perform PVP on patients on antiplatelet medications but prefer men on warfarin to bridge to heparin, with no anticoagulation given around the time of the surgery.

Complications

Intraoperative and Perioperative. Overall, the safety profile of the PVP technology is excellent. TUR syndrome is not reported in any series because normal saline is used as irrigation. Blood transfusion is exceedingly rare, and patients on anticoagulation do not appear to be at a significantly increased risk. PVP had a lower risk (OR 0.10) for perioperative blood transfusion when compared with M-TURP (Cornu et al, 2014). Capsular perforation has been reported with PVP with ranges of 0.2% to 1% of cases (Rieken et al, 2010). Some surgeons may find the visualization of the capsule more difficult with the PVP, particularly early in the learning curve. Maintaining a proper sweeping motion and serially removing tissue in a circumferential fashion will avoid irregularities in vaporization depth and avoid perforation. If capsular perforation occurs, increased bleeding is usually noted and conversion to TURP is more common (Bachmann et al, 2012). Although rates are largely unreported, ureteral orifice injury can occur from errant laser energy. The ureteral orifices should be identified before beginning the vaporization; taking care to not extend the fiber into the bladder when vaporizing the bladder neck should minimize the possibility of this occurring.

Postoperative. Postoperative dysuria and storage symptoms are fairly common after PVP. In large series examining these outcomes, the adverse events were usually self-limiting, resolving either spontaneously within 3 months or with the help of anti-inflammatories or antibiotics. The reported incidence of these symptoms ranges from 0% to 25.7% and is, in general, higher than data reported from TURP studies (Naspro et al, 2009). As stated earlier the inefficient use of laser energy should be minimized in an effort to decrease this risk to patients. In a small series of patients, Matoka and Averch (2007) found that preoperative finasteride use and lower preoperative AUASS were predictors of postoperative irritative symptoms.

Infectious complications may be more common after PVP owing to the necrotic tissue that occurs with coagulation. Epididymitis has been reported in 5% to 7% of patients; UTI has been reported in 1% to 20% of patients (Chughtai and Te, 2011). Treatment of these conditions may be more challenging because of the presence of the necrotic tissue and its ability to harbor and feed bacteria. The treating physician should consider longer courses of antibiotics in these patients.

Because the sheath used for PVP is typically smaller than those customarily used for TURP, the risk of urethral stricture should be lower. The surgeon should minimize movements of the sheath, with a preference for laser fiber movement to further lower this risk. Only 2.8% of patients had urethral stricture, and an RR of 0.65 was calculated compared with TURP (Thangasamy et al, 2012). A more recent meta-analysis did not verify this finding; comparable rates of stricture (and bladder neck contracture) were found between 120-W PVP and M-TURP (Cornu et al, 2014).

Reoperation rates specifically for residual adenoma vary significantly based on study type and laser power. In their summary of PVP technology, Gravas and colleagues (2011) compared the reoperation rates of 80-W KTP with TURP at different time frames. After 6 months the rates were 18% versus 0%; 10% versus 3.4% after 12 months; and 6.7% versus 3.9% after 24 months for PVP and TURP,

respectively. Other authors have found rates of 7.7% (Hai, 2009) and 6.8% (Ruszat et al, 2008) at 5 years, although both studies had high attrition rates. In an analysis of only 120-W studies, a slight increase in need for reoperation for residual BPH was found, but the authors commented on an overall small sample size (Cornu et al, 2014).

In the large XPS series by Bachmann and colleagues (2012), 10% of patients developed dysuria despite high laser energies used. Although it was a short-term study, incidence of re-treatment for residual adenoma was only 0.5% and of postoperative retention was only 2.8%. Temporary incontinence was observed, but fairly rarely (5.8%). At least partial conversion to TURP was influenced by prostate size; 2%, 6.5%, and 16% of resections required this in prostate volumes of below 40 mL, 40 to 80 mL, and more than 80 mL, respectively.

Changes in erectile function in patients undergoing PVP are still being more clearly elucidated; however, early results are encouraging. In 105 men undergoing PVP who completed the Sexual Health Inventory for Men (SHIM) preoperatively and 12 months after surgery, there was clearly no worsening of erectile function. In those men who were catheter free before surgery, statistically insignificant improvements were seen in erectile function (Kavoussi and Hermans, 2008). Mild but statistically significant improvements were noted in all IIEF-15 subdomains in a similarly structured trial of 45 men (Paick et al, 2007).

Conclusion. The early laser techniques focused on coagulation. More contemporary techniques use laser power to vaporize large portions of the prostate in an essentially bloodless field. While coagulation is still part of the laser vernacular, a de-emphasis on broad coagulation has resulted in reduced postoperative irritative symptoms with a preference for laser technology that chiefly leads to prostate vaporization.

The early and lower-power PVP technology appears to have been less efficient against larger prostate glands, with long operative times and high re-treatment rates. However, the excellent hemostasis and vaporization of PVP have allowed for the treatment of many challenging patients, such as those on anticoagulation, that has not been attempted with many other endoscopic modalities for treatment of BPH.

Thulium

Overview and Concept. The thulium:yttrium-aluminum-garnet (Tm:YAG) laser is a continuous wave of 2013-nm energy and has recently been introduced for the treatment of BPH. With a similar wavelength to the holmium laser, this energy undergoes absorption in the irrigant but without the intermittent nature of holmium. The continuous energy emission has been suggested to lead to a cleaner incision, and with a slightly shorter wavelength than holmium, absorption by tissue is theoretically more pronounced and efficient (Chung and Te, 2009). However, such claims are putative until scientific proof is offered. As the emitted wavelength reaches closer to the ideal in soft tissue, theoretically there will be a decrease in scattered thermal damage (Schomacker et al, 1991), which may lead to decreased scarring and stricture formation. However, in an animal model there was a wider thermal damage zone than predicted, similar to that seen with holmium (Fried and Murray, 2005).

Technique. As with other laser technologies, thulium may be used to either vaporize or incise tissue, although the early clinical use has been to incise tissue to enucleate the transition zone of the prostate. This technology has introduced a new technique wherein the prostatic lobes are “peeled” like a tangerine off the prostatic capsule (Xia, 2009). The anatomy followed during prostate enucleation with thulium is similar to that followed during HoLEP. The procedure is essentially analogous to HoLEP, including morcellator use when the surgeon selects this option.

Some authors have used a resection-type technique wherein multiple incisions are made in the prostate parenchyma down to the capsule. Smaller sections of prostate are then liberated from the capsule, leading to small prostate chips that can be irrigated through the resectoscope sheath. This eliminates the need for using the often

troubling morcellator. Catheter drainage is maintained at least overnight and can customarily be removed once hematuria has resolved (usually 1 to 3 days postoperatively). Patients can usually be discharged home the same day as catheter removal.

Outcomes

Single-Cohort Series. In an early retrospective review of the technology, 56 patients were reviewed (Szlaue et al, 2009). Maximum flow at day of discharge was improved from 8.1 mL/sec to 19.3 mL/sec, with a decrease in average residual urine to 57 mL from 151 mL. At a median follow-up of 9 months, PSA was reduced by 56% and the AUASS decreased from 19.8 to 8.6. The authors pointed out a slightly lower acquisition cost for the thulium compared with holmium. They did estimate that 56% to 70% of the tissue was removed by their “vaporesection” approach compared with the 30% to 85% for HoLEP.

Bach and colleagues (2010) reviewed patients who underwent enucleation and morcellation (“vapoenucleation”) with at least 12 months of follow-up. At 12 months, maximum urinary flow rate improved from 3.5 to 23.3 mL/sec (range of 6.6 to 47.9 mL/sec). AUASS decreased from 18.4 to 6.8, and QoL score improved from 4.6 to 1.5. Patients who had preoperative TRUS volume greater than 60 mL were not more likely to have improvements in voiding parameters.

In a study looking exclusively at patients with prostate volumes greater than 75 mL, with 70% having a volume greater than 100 mL, the AUASS decreased from 21.1 to 3.9, with a 248% increase in maximum flow. Mean prostate volume assessed by TRUS decreased from 108 to 13.8 mL. PSA had a similarly large decrease from 9.53 to 0.93 ng/dL, and IIEF score improved by 1 point with treatment (Iacono et al, 2012). Taken as a whole, the improvements seen with these thulium-based removals of the transition zone are largely equivalent to those seen with HoLEP.

Comparative Series

Thulium Resection versus Transurethral Resection of the Prostate. In a trial comparing standard M-TURP with thulium resection, 100 patients were randomized (Xia et al, 2008). Thulium treatment was superior with regard to catheterization time, hospital stay, and hemoglobin change with surgery. Treatment times were similar. Changes in symptom scoring and urodynamic findings had comparable changes; rates of late complications were also similar. A total of 158 patients were evenly randomized to receive either B-TURP or thulium enucleation in the report published by Yang and colleagues (2013). Operative time was 18 minutes longer in the thulium group, but significant decreases were noted in catheterization and hospital days with thulium resection. AUASS, QoL score, Qmax, and PVR had similar outcomes between groups even out to 18 months.

Tang and colleagues (2014) performed a systematic literature review and meta-analysis of studies comparing TURP and thulium resection. Both randomized and nonrandomized trials were included, along with both M-TURP and B-TURP. These researchers found a statistically significant longer operative time in the thulium group, although the clinical significance of the 9-minute weighted mean difference is likely inconsequential. Neither technique displayed consistent superiority with regard to AUASS, QoL score, PVR, or Qmax. The authors were also able to analyze complication rates and found decreased odds of receiving transfusion with thulium resection (OR 0.28, $P = .04$). Complications they deemed as “local,” including need for recatheterization, incontinence (stress or urge), UTI, and retrograde ejaculation, did not have significant differences between treatment options. Thulium did seem to display lower odds of developing urethral stricture (OR 0.29, $P = .007$).

Thulium Enucleation versus Holmium Laser Enucleation of the Prostate. A randomized comparison of thulium and holmium enucleation was published by Zhang and colleagues (2012). A total of 133 consecutive patients were randomized to a similar enucleation technique with the different fibers at a single center. Thulium required a longer operation time by approximately 10 minutes and had similar outcomes with regard to postoperative AUASS, Qmax, and PVR. PSA reductions were more modest than in most other enucleation studies (30% in the HoLEP group and 43% in

the thulium group) but were not statistically different when compared. Complications were sparsely reported, but there was no appreciable difference in catheterization times.

Complications

Intraoperative and Perioperative. The learning curve associated with thulium resection of the prostate has not been adequately studied, but it is safe to assume that it will be similar to that of HoLEP. Most studies did not report or did not have any intraoperative complications. In a study using the morcellator for evacuation of prostate lobes after enucleation, no patients experienced incomplete morcellation or ureteric orifice injuries, but 1.3% had bladder wall injuries caused by the morcellator (Iacono et al, 2012).

Postoperative. Early complications were analyzed by Bach and colleagues (2010), who defined rates of symptomatic UTI (6.8%), bleeding (5.6%), and immediate re-treatment for residual BPH (2.2%). Blood transfusion was required in 2.2% of patients. Mild storage symptoms were observed frequently (27%), but most resolved within 1 month of surgery. They found that with a cutoff prostate size of 60 mL there was no difference in rates of complications based on prostate size.

In one of the first thulium enucleation studies published, a prohibitively high reoperation rate of 10.7% was seen in the relatively short follow-up period (Szlaue et al, 2009). The most common was need for reoperation for residual prostate hyperplasia and was attributed primarily to the learning curve associated with the procedure because all of these occurred within the first 20 cases. The authors used a technique wherein the prostate is resected off the capsule in small pieces (vaporesection, not true enucleation) and commented that they felt the learning curve for this technique would be shorter than that for HoLEP.

In their series of large prostates (all greater than 75 mL) undergoing thulium resection, 2.7% of patients required early recatheterization after surgery. Continued postoperative hematuria resulted in 2.7% of patients requiring blood transfusion. Transient urge incontinence was noted in 6.7% of patients, but it had resolved in all at 1 year of follow-up. UTI was reported in 12.8% (Iacono et al, 2012).

Conclusions. Initial results from this new laser technology are encouraging. It appears that there is potentially an improvement in tissue removal rate compared with other technologies owing to the combined vaporization and incision that occurs with this technology. Theoretically it may have advantages compared with holmium enucleation with regard to tissue interaction, but certainly more populated and longer studies are required to evaluate this newcomer.

KEY POINTS: LASER TREATMENTS

- Laser treatments are the fastest growing option in treatment of LUTS and BPH but should be used as part of a culture of safety in the operating room.
- HoLEP is a very effective treatment option with excellent results that are often comparable to those historically seen with OP. There is a significant learning curve associated with the procedure, and catastrophic complications (mostly caused by the morcellator) have been observed.
- PVP is a growing and very safe treatment option for BPH and LUTS. Results in patients on anticoagulation have been encouraging.
- Thulium is the newest addition to the laser family and has some theoretical advantages, although scientific data are lacking.

Failed, Failing, and Future Directions

See the Expert Consult website for details.

CONCLUSION

Although OP and M-TURP had high complication rates, they did provide excellent treatment for the age-old problem of LUTS and BPH. Many new suitors have been introduced to the market in an effort to achieve maximum results with a more acceptable safety profile, but each new technology has led to previously unconsidered complications and new paradigms to consider. The trainee and even veteran urologist should be conscientious to carefully examine the results of each new treatment because new studies too frequently attempt to mislead or overstate their results by not including a rigorous design or adequately controlling for a placebo effect.

In reality, the gold standard operation for any patient is the one that meets his needs and expectations while still being safe. This decision should include a careful consideration of the patient factors, but the surgeon's familiarity with and ability to safely perform the selected procedure should also be factors.

Prostate Stents

Concept. The concept of placing a stent into the prostate for relief of infravesical obstruction has a long track record. Stents can be classified into many categories including temporary or permanent, epithelializing, or nonepithelializing. In general, the temporary varieties are used to combat the edema that accompanies many of the minimally invasive treatment options and are removed when the edema has resolved. Although previously used in a wide variety of patients, permanent stents have largely been relegated to use in older men with medical comorbidities that severely restrict their treatment options because of the inability to tolerate any level of anesthesia.

The mechanism of action of these prostatic stents is straightforward: The stent provides a rigid framework that, once in place in the prostatic fossa, pushes outward to open the prostatic lumen. In the epithelializing version, the stent is incorporated into the urethra as the urothelium grows into the stent, which should prevent encrustation or migration. Stents have been commonly used for treatment of the enlarged prostate; other indications wherein stents have been used in the urethra include the treatment of detrusor-sphincter dyssynergia (Chancellor et al, 1999; Chartier-Kastler et al, 2000; Gajewski et al, 2000), postbrachytherapy obstruction (Konety et al, 2000), and complications of radical prostatectomy (Meulen et al, 1991).

The no longer produced UroLume (American Medical Systems) was an epithelializing permanent stent that was made of alloy wire in a woven shape that could expand to 42 Fr within the prostatic urethra. It came in varying lengths, with a stent as short as 1.5 cm. Because of some of the shortcomings with this stent (e.g., incomplete epithelialization leading to encrustation, stent migration), second-generation stents were developed including the Memokath (Engineers and Doctors A/S, Hornbaek, Denmark). These spiral stents would expand when flushed with hot water, with a portion of them being secured at the prostatic apex.

Data. Initial clinical trials in the United States and Europe demonstrated efficacy in treatment of LUTS caused by BPH. In a study headed by Oesterling and colleagues (1994), patients were grouped into those with urinary retention and those without retention. In the nonretention group, 80 of the 95 patients were able to be evaluated at 12 months, and 52 had data available at 24 months. The Madsen symptom score decreased from a modest 14 to 5.9 and 5.4 at 12 and 24 months. The maximum urinary flow increased from 9.1 to 13.0 and 13.1 mL/sec, respectively. In the retention group, a mean Madsen symptom score of 6.1 was noted at 12 months. This group had a Qmax of 11.7 mL/sec at 1 year post-treatment.

The European equivalent of this study examined 135 healthy men, of whom roughly a third had retention (Guazzoni et al, 1994). In the nonretention group, the Madsen score decreased from 14.1 to 6.4 at 12 months; Qmax increased from 9.3 to 15.7 mL/sec. In the retention group, the mean symptom score was 4.5 after stent placement and the Qmax was 13.1 mL/sec.

Masood and colleagues (2004) reported on 62 men with follow-up of 12 years. A total of 47% of the stents were removed for a variety of reasons including malpositioning, migration, and patient dissatisfaction. Most (62%) of these removals occurred within the first 2 years after stent placement. The authors cautioned the use of careful case selection and surgeon experience.

In a review of results (Armitage et al, 2007) with the UroLume, of 176 men who could be identified as depending on catheterization before stent placement, 84% were able to void spontaneously after stent placement.

Perry and colleagues (2002) reported on the use of a Memokath stent in 211 men who were unfit for surgery; a reduction in AUASS of 59.6% was present at 3 months, with almost no change in the next 7 years. It is interesting to note that these frail older men were more likely to die with their stent in situ (38%) than to require removal (23%).

Conclusion. Although originally a popular procedure for men unfit for surgery, the clinical application broadened, but eventually the procedure was abandoned except as a palliative treatment or in

patients who are unable to tolerate any other procedure owing to medical comorbidities. The high failure and removal rates, with an often difficult removal, were overall prohibitive, especially compared with many other suitable options.

Prostate Urethral Lift

Concept. The prostatic urethral lift (PUL) is marketed under the name UroLift (NeoTract, Pleasanton, CA) and is a new treatment option for BPH that works by altering prostatic anatomy without ablating tissue. These permanent transprostatic implants take the forms of sutures that are delivered by a handheld device through a cystoscope to mechanically open the prostatic urethra by compressing the prostate parenchyma (Fig. 105-16). The sutures have T-shaped bars on the ends of the suture and are spring loaded and placed so that the bars are set with one outside the prostate and the other within the prostatic urethra lumen. The suture is placed on tension and once activated pulls the lumen of the prostatic urethra toward the capsule, opening the prostatic urethral lumen. The bar within the urethra is quickly covered by a re-epithelialized urethra so that the device is not exposed to the urinary tract for an extended period. In harvested tissue after implantation the biologic response to the implant was benign (Woo et al, 2011).

The particular advantages of this technology include the low rates of local symptoms along with a minimization of any impact on sexual factors such as ED and ejaculatory problems. Because

Figure 105-16. A and B, Placement of UroLift. (Courtesy NeoTract, Inc.)

the procedure is nonablative and the urethral mucosa largely stays intact, there should be a minimization of dysuria and other storage symptoms along with more severe complications such as bladder neck contracture and postoperative incontinence. The implants are placed anterolaterally in the prostate, so injury to the neurovascular bundles or dorsal venous complex should not occur (Fig. 105-17). The bladder neck is largely unaffected; therefore ejaculatory function should not be hindered.

The procedure is done through a rigid cystoscope sheath and can typically be done in the office setting with only local anesthesia. Overall, the procedure is well tolerated with minor and self-limited postoperative adverse events.

Data. A prospective, randomized trial evaluated a total of 206 men, with 140 undergoing PUL and 66 undergoing a sham procedure (Roehrborn et al, 2013). Unblinding occurred at 3 months after procedure; the study group was then followed to 1 year. The mean procedure time was 66 minutes. In the North American arm, 99% of the procedures were completed using local anesthesia. Patients in the PUL group experienced AUASS reduction from 22 at baseline to 18, 11, and 11 at 2 weeks, 3 months, and 12 months, respectively (all $P < .001$). Maximum flow rates in the PUL group were improved by 4.4 mL/sec at 3 months and 4.0 mL/sec at 1 year, which were both statistically significant compared with baseline.

In comparison of groups at 3 months, changes in AUASS in the treatment group were 88% greater than in the sham group ($P = .003$). Reductions were noted in both storage and voiding symptoms. No perioperative adverse events were recorded in either group, but procedure-related adverse events appeared to be more common in the PUL group, with the most common being dysuria (34%), hematuria (26%), and pelvic pain or discomfort (18%).

Further publication from this study group evaluated changes in sexual function (McVary et al, 2014a). There was no evidence of erectile or ejaculatory dysfunction after PUL, and questionnaire scores were modestly improved and statistically different from baseline at 1 year. Ejaculatory bother was most improved, with a 40% improvement seen compared with baseline. SHIM score was most improved in men with severe ED at baseline. This larger study verified the findings previously published in initial testing (Woo et al, 2012).

Durability at 2 years was demonstrated by Chin and colleagues (2012). They reported a 42% improvement in AUASS in patients evaluated at 2 years. Peak flow was improved at a minimum of 30% compared with baseline at all follow-up intervals.

Verdict. This is a promising new addition to the urologist's armamentarium. Theoretically it offers many advantages over many currently used BPH procedures. Despite ease and convenience, the

usefulness of the more minimally invasive options usually is limited by their long-term durability, with often unacceptable need for re-treatment. As long-term data become available from the initial trials, the urologic community will better understand the role of prostate urethral lift in the treatment of BPH.

Prostate Embolization

Concept. After the first reported case by DeMeritt and colleagues (2000), this procedure did not gain more widespread use until recently. In general, access is gained at one of the femoral arteries and pelvic angiography is performed to evaluate the iliac tree and prostatic arteries. Once the catheter has been advanced into the prostatic arteries, an embolizing agent (alcohol, microspheres) is then infused through the catheter until stasis is seen in the prostatic vessels. Although usually just one femoral access is gained, the procedure can be done on the prostatic vessels either unilaterally or bilaterally, although it appears the bilateral procedures incur better results (Bilhim et al, 2013).

As seen commonly with embolization of blood-rich organs (e.g., kidney), a postembolization syndrome of pain and fever is customary. As tissue is not directly removed or ablated, there should be minimal other local symptoms; however, gaining the access to the femoral vessels may lead to local problems at that area including pseudoaneurysm or bleeding (Stone and Campbell, 2012). In addition, intravascular contrast agents are used, making a contrast allergy a contraindication. The angiography needed during this procedure opens the patient up to a sometimes surprising radiation exposure.

Possible technical problems are the inability to access the prostatic arteries because of tortuosity, vessel atherosclerosis, or aberrant pelvic arterial anatomy. In the study by Bilhim and colleagues (2012), the prostatic artery was found to arise from five different arterial trunks, with the most common site being the internal pudendal artery (34%). In 43% of the patients, there were two prostatic arteries on one side. Anastomoses to adjacent arteries were commonly found.

Data. In one of the early, small published series, modest but statistically significant improvements in AUASS were seen (6.5 points, $P = .005$) at a mean follow-up of 7.9 months. Peak urinary flow increase was only 3.85 mL/sec ($P = .015$), with a reduction of 26% in PSA and 27% in prostate volume. The procedure was unable to be completed in 6.7% of patients, and 28.6% of patients met criteria for clinical failure. There was one major complication, which included an ischemic area of the bladder wall. Mean procedure time was 85 minutes (range 25 to 135), with patients undergoing a mean fluoroscopy exposure time of 35 minutes (range 15 to 45 minutes) (Pisco et al, 2011). After the learning curve has been overcome, one author estimated the procedure can routinely be done in 90 to 120 minutes (Carnevale and Antunes, 2013).

A total of 11 patients with urinary retention were studied by Antunes and colleagues (2013). Ten of the 11 patients were catheter free at a minimum follow-up of 1 year with a mean AUASS score at that time of 2.8 (range 1 to 7). UDS was performed before and after treatment. PdetQmax decreased from a mean of 85.7 to 51.5 cm H₂O. All patients had a BOOI of greater than 40 before treatment, with only 30% being clearly unobstructed (BOOI <20) and 40% characterized in the equivocal range (BOOI 20 to 40). Almost all patients reported mild, transitory pelvic pain; 3 patients had minor rectal bleeding.

In a trial done in the United States, 72 patients were screened and 20 met inclusion criteria. At 3 months post-procedure, a 49% reduction in AUASS was noted in the 13 patients supplying data. In patients with at least 6 months of follow-up ($n = 5$), prostate volume decreased by an average of 18%. The procedure lasted on average 72 minutes, with an average of 30 minutes of fluoroscopy time (Bagla et al, 2014). In another report, criteria for qualifying for the procedure allowed only approximately one third of patients seen in initial consultation to proceed (Pereira et al, 2012).

Later, larger series became available, although most data is concentrated from a small number of centers. A prospective study of

Figure 105-17. Placement of implants (I) in the anterolateral position in the prostate between the dorsal veins (DV) and neurovascular bundles (NV). (Courtesy NeoTract, Inc.)

255 patients was published by [Pisco and colleagues \(2013\)](#) recently. Technical success (defined as bilateral arterial occlusion) during the procedure occurred 97.9% of the time. The procedure itself was not painful in 76% of cases, with only one patient reporting severe pain during the procedure.

Clinical success was uniquely and capriciously defined as an improvement in AUASS of at least 25% of the initial score and a score lower than 18. Patients started with a large range of preprocedural AUASS scores (range 4 to 35) and had a mean prostate volume of 83.5 mL with a mean maximum flow of 9.2 mL/sec. Cumulative rates of clinical success were 82%, 81%, 78%, 75%, 72%, 72%, 72%, and 72% at 1, 3, 6, 12, 18, 24, 30, and 36 months, respectively. Clinical failure seen at 1 month had no direct correlation with the reduction in prostate volume; however, it appeared that failures were more common if only unilateral embolization occurred.

At 3 months, the mean AUASS was reduced by 54% and the QoL score by 49%. Over the same period, maximum flow improved by 35%, prostate volume shrunk by 18%, and IIEF score improved by 10.6%. In those patients with data at 1 year after the procedure, the absolute scores were not appreciably different than those at 3 months. Despite the fact that the urinary tract was not entered, 7.6% of patients received antibiotics for a UTI, although many of these patients were possibly infected at the time of the procedure. Other adverse events such as rectorrhagia (2.4%), AUR (2.4%), and hematospermia (0.4%) were transient in nature.

Verdict. A technically challenging and highly variable pelvic anatomy may limit the widespread acceptance of this technology, with only expert interventionists performing the procedure. Completed studies have largely been nonrigorously performed, and the application of the generated data makes it difficult to predict the role of prostate embolization in the treatment of LUTS and BPH. The many problems with these embolization reports include (1) a reliance on imaging-based reduction in prostate volume, (2) naive prostatic-centric concepts of BPH, (3) lack of control patients, (4) an unconventional definition of clinical improvement, (5) uniform failure to account for a placebo effect, thus leading one to assume that the improvement in LUTS or other outcomes were related to prostatic embolization (intervention effect remains unknown), and (6) ignoring LUTS as the motivating complaint and the ultimate arbitrator of success.

Prostatic Injections

Concept. References to intraprostatic injection for management of prostate disease date back more than 100 years ([Plante et al, 2004](#)). The ease of application and overall low start-up costs make this an attractive option. An injectable is commonly administered via a transperineal or transurethral approach into the prostatic parenchyma, with the injected substance theoretically causing localized changes to reduce prostate volume.

A wide variety of solutions have been tried in animal models. Agents reported to have been used in human studies include acid mixtures ([Talwar and Pande, 1966](#)), pepsin-iodine concoctions ([Payr, 1936](#)), ethanol, and now botulinum neurotoxin type A (BoNTA). Historically, anhydrous ethanol was the most widely studied injectable, but BoNTA has been more widely studied in the last few years.

Data

Anhydrous Ethanol. Anhydrous ethanol treatments of the prostate for LUTS and BPH have been primarily studied in non-U.S. markets. Investigative trials are underway in the United States to allow ethanol to formally gain FDA approval for the use in the prostate ([Plante et al, 2007](#)). Although the mechanism of action with human prostate cells is not entirely delineated, it is likely that there are proapoptotic mechanisms that are induced ([Plante et al, 2013](#)). Other possible mechanisms include hemorrhagic coagulation necrosis caused by vessel thrombosis and occlusion ([Goya et al, 1999](#)).

In a study of 35 patients with a mean follow-up of 50 months (range 47 to 56 months), initial significant changes were noted in

AUASS (−75%), Qmax (+247%), and prostate volume (−30%) at 3 months ([Sakr et al, 2009](#)). At 4-year follow-up, 25 of the initial 35 patients had data for reporting; improvements compared with pre-injection data were 55% in AUASS, 187% in Qmax, and 5.2% in prostate volume. Nine patients (26% of the initial cohort) required some form of re-treatment (TURP, reinjection, or medical therapy) during the study period. In a study with a long follow-up but a high attrition rate, 23% of patients required alternative treatment ([El-Husseiny et al, 2011](#)).

In 36 patients followed to 1 year after treatment, AUASS (46% reduction) and QoL scores (48% reduction) were significantly decreased at last visit. Maximum flow improved throughout the study period, with improvements significant at 3 months (78%), 6 months (137%), and 12 months (154%). Reports on potential nonresponders and patients needing re-treatment were not included, and it was unclear if these were consecutive patients ([Magno et al, 2008](#)).

In a phase I/II trial evaluating varying doses of ethanol injection, the most common reported adverse events were hematuria (42%), irritative voiding symptoms (39%), pain and discomfort (28%), and transient urinary retention (22%) when absolute reporting was used ([Plante et al, 2007](#)). However, when stratified to AUA guidelines, these percentages were 0%, 2.7%, 5.4%, and 16.2%, respectively. Patients were randomized to a low, medium, or high dose adjusted for prostate size and had a roughly 50% decrease in AUASS and QoL scores across doses. Injection was done transurethrally; the average procedure lasted 25 minutes. Moderate or severe pain during the procedure was reported by 6.7% and 12.2% of patients, respectively.

Botulinum Toxin. BoNTA is produced by *Clostridium botulinum* and has an already established use in urology for the care of patients with neurogenic voiding dysfunction. Although the exact mechanism to improve voiding when injected into the prostate is not completely understood, this exotoxin may have influence over both the static and dynamic components of BPH ([Chuang et al, 2006a](#)). In a placebo-controlled animal study, male rats 1 week after BoNTA injection were noted to have an increase in apoptotic cells with decreases in proliferative cells and the α_{1A} receptor. No significant change was noted in the presence of the androgen receptor. In rats killed 2 weeks after injection, these effects were less notable ([Chuang et al, 2006b](#)). This validated an earlier study wherein BoNTA injection led to a generalized apoptotic atrophy of the rat prostate thought to be caused by denervation ([Doggweiler et al, 1998](#)). In an interestingly designed study, [Silva and colleagues \(2009\)](#) concluded that BoNTA induced prostate atrophy in the rat that could have been the result of sympathetic nerve impairment, with the data indirectly suggesting that sympathetic neural drive played a role in prostate size regulation.

A dose response was established by [Lin and colleagues \(2007\)](#), who studied the effects of two doses of BoNTA (100 U and 200 U) on prostatic contractile function and structural changes. The higher dose produced a more pronounced atrophic change in the smooth muscles cells of the dog prostate. Under electrostimulation, prostate urethral pressure response was statistically lower in only the 200-U group.

A placebo-controlled trial in humans found a 65% reduction in AUASS at 2 months after injection. PSA was reduced by 51% and prostate volume was reduced by 68% compared with baseline, corroborating the findings of induced cell atrophy seen in animal studies ([Maria et al, 2003](#)). Of the 15 patients receiving BoNTA injection, 13 noted improvements in voiding. No patients in the placebo group experienced benefits from saline injection. Four control group patients later received BoNTA, with 17 patients having longer follow-up data. Reductions in AUASS, serum PSA, peak flow rate, and prostate volume appeared durable at 1 year.

In a cohort of 60 patients with a prostate volume of over 60 mL with an unsatisfactory response to combination medical therapy, 30 were randomized to BoNTA injection ([Kuo et al, 2009](#)). Although injection did reduce prostate volume and improve AUASS and QoL scores, the long-term therapeutic benefits were minimal compared with the control group. At 6 and 12 months after injection, only

the QoL score in the study group was statistically different than in the group continuing combination therapy. At the end of the study, 3 patients in the treatment group and 2 patients in the control group progressed to TURP for relief of LUTS. Surprisingly, despite not receiving any placebo drug or sham procedure, the control group had statistically significant improvements in AUASS, QoL scores, and prostate volume at 6 and 12 months.

A phase II dose-ranging placebo-controlled RCT was published in 2013 (Marberger et al, 2013). Significant improvements from baseline values were found in AUASS, maximum flow, and prostate volume at 12 weeks in all groups (including normal saline placebo). No significant differences were found between the doses of BoNTA and placebo. Adverse events were comparable across study groups.

A multicenter, double-blind, sham-controlled study verified these results and included 315 patients (McVary et al, 2014b). Whereas decreases in AUASS were seen in both the BoNTA (−6.3) and placebo (−5.6) groups, there was no difference between BoNTA and placebo. The authors concluded that although the treatments

were well tolerated, no increased efficacy was seen with BoNTA over saline injection.

Verdict. Anhydrous ethanol will still need to gain FDA drug approval in the United States before widespread acceptance. The low start-up cost and relative ease of delivery compared with other BPH treatment options will likely make this a very successful treatment option in developing nations and areas with otherwise sparse urologic care. Full acceptance in developing nations will likely depend on the comparative clinical efficacy. Re-treatment rates from preliminary reports appear to be prohibitively high for widespread acceptance in areas with a diversity of treatment options.

BoNTA is a new treatment option with an already established record for use in urology. Although the exact mechanism of action is still debatable, published results continue to help us further understand the importance of neural input to the prostate. Data from RCTs have provided unexceptional results with unexpectedly positive control group effects.

Surgical Technique

Postoperative Management

Complications

Summary

The treatment options for bladder outlet obstruction resulting from benign prostatic hyperplasia have been expanded dramatically over the past 2 decades with the development of medical and minimally invasive therapies. The current medical therapies for lower urinary tract symptoms include selective long-acting α_1 -adrenergic antagonists, such as terazosin (Hytrin) (Lepor, 1995; Roehrborn et al, 1996), doxazosin (Cardura) (Gillenwater et al, 1995), tamsulosin (Flomax) (Abrams et al, 1995), and alfuzosin (Uroxatral) (Jardin et al, 1991; Buzelin et al, 1997), and the 5 α -reductase blockers, such as finasteride (Proscar) (Gormley et al, 1992; Andersen et al, 1995; Lepor et al, 1996), and dutasteride (Avodart) (Roehrborn et al, 2002, 2004). Minimally invasive procedures include visual laser ablation of the prostate (Cowles et al, 1995), transurethral electrovaporization of the prostate (Kaplan et al, 1996), transurethral needle ablation (Schulman et al, 1993; Campo et al, 1997), transurethral microwave thermotherapy (Ogden et al, 1993; Javle et al, 1996), interstitial laser coagulation (Muschter and Hofstetter, 1995), bipolar transurethral resection of the prostate (bipolar TURP) (Botto et al, 2001; Eaton and Francis, 2002), and transurethral incision of the prostate (Cornford et al, 1997). However, these approaches are usually reserved for men with moderate symptoms and a small- to medium-sized prostate gland (Reich et al, 2006). For larger prostate glands, open simple prostatectomy has been frequently performed. Lately, holmium laser enucleation of the prostate (HoLEP) with the holmium:yttrium-aluminum-garnet (Ho:YAG) laser has been performed as a minimally invasive alternative to open surgery (Gilling et al, 1998). However, the learning curve with HoLEP is considered steep (Razzak, 2013). Most recently, as urologists have gained experience in minimally invasive therapy, a simple prostatectomy has been performed more frequently using a laparoscopic or robotic approach (Sotelo et al, 2005, 2008). This chapter describes simple prostatectomy technique using an open and robot-assisted laparoscopic approach.

For patients with acute urinary retention, persistent or recurrent urinary tract infections (UTIs), severe hemorrhage from the prostate, bladder calculi, severe symptoms unresponsive to medical therapy, and/or renal insufficiency as a result of chronic bladder outlet obstruction, TURP or simple prostatectomy is indicated. When compared with TURP, simple prostatectomy offers the advantages of lower re-treatment rate and more complete removal of the prostatic adenoma under direct vision and avoids the risk for dilutional hyponatremia (the TUR syndrome) that occurs in approximately 2% of patients undergoing a traditional monopolar TURP (Mebust et al, 1989; Roos et al, 1989). Several contemporary series have demonstrated objective improvement in urinary

symptoms after simple prostatectomy (Tubaro et al, 2001; Gacci et al, 2003; Varkarakis et al, 2004). The disadvantages of open simple prostatectomy, compared with those of TURP, include the need for a lower midline incision and a resultant longer hospitalization and convalescence period. There also may be an increased potential for perioperative hemorrhage (Serretta et al, 2002). However, robot-assisted laparoscopic simple prostatectomy results in a significantly decreased risk for perioperative hemorrhage and transfusion (Clavijo et al, 2013).

Open simple prostatectomy can be performed by either the retropubic or the suprapubic approach. In retropubic prostatectomy the enucleation of the hyperplastic prostatic adenoma is achieved through a direct incision of the anterior prostatic pseudocapsule. This approach to open simple prostatectomy was popularized by Terrence Millin (1945), who reported the results of the procedure on 20 patients in *The Lancet* in 1945. The advantages of this procedure over the suprapubic approach are (1) excellent anatomic exposure of the prostate, (2) direct visualization of the prostatic adenoma during enucleation to ensure complete removal, (3) precise transection of the urethra distally to preserve urinary continence, (4) clear and immediate visualization of the prostatic fossa after enucleation to control bleeding, and (5) minimal to no surgical trauma to the urinary bladder. The disadvantage of the retropubic approach, as compared with the suprapubic prostatectomy, is that direct access to the bladder is not achieved. This may be important when one considers excising a concomitant bladder diverticulum or removing bladder calculi. The suprapubic approach also may be the preferred method when the obstructive prostatic enlargement includes a large intravesical median lobe.

Suprapubic prostatectomy, or transvesical prostatectomy, consists of the enucleation of the hyperplastic prostatic adenoma through an extraperitoneal incision of the lower anterior bladder wall. This approach to open prostatectomy was first performed by Eugene Fuller in New York in 1894; it was later popularized by Peter Freyer in London, England, who described the procedure in 1900 and later reported the results of his first 1000 patients in 1912 (Freyer, 1900, 1912). The major advantage of this suprapubic procedure over the retropubic approach is that it allows direct visualization of the bladder neck and bladder mucosa. As a result, this operation is ideally suited for patients with (1) a large median lobe protruding into the bladder, (2) a clinically significant bladder diverticulum, or (3) large bladder calculi. It also may be preferable for obese men, in whom it is difficult to gain direct access to the prostatic pseudocapsule and dorsal vein complex (Culp, 1975). The disadvantage, compared with the retropubic approach, is that direct visualization of the apical prostatic

adenoma is reduced. Furthermore, hemostasis may be more difficult because of inadequate visualization of the entire prostatic fossa after enucleation.

Since the performance of the initial laparoscopic radical prostatectomy in 1997 (Schuessler et al, 1997) and the introduction of the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) in 2000, the minimally invasive approach, especially the robotic approach, for radical prostatectomy has gained wide popularity. As urologic surgeons gain more experience with the robotic instruments, the robot-assisted laparoscopic simple prostatectomy has been gradually gaining acceptance (Sotelo et al, 2008; Yuh et al, 2008; John et al, 2009). The major advantages of the robot-assisted laparoscopic simple prostatectomy approach over the open approaches are excellent hemostasis, negligible need for transfusion, shorter hospital stay, and better visualization because of pneumoperitoneum and magnification (Matei et al, 2012). This approach also can manage a large median lobe, bladder diverticulum, or large bladder stones. The disadvantages of robot-assisted laparoscopic simple prostatectomy, compared with the open approaches, include the need for a general anesthesia, a steep learning curve, and a longer operative time, especially in the initial experience (Matei et al, 2012). Therefore the robotic simple prostatectomy approach should be considered by urologic surgeons who have extensive experience in robotic surgery, especially in robot-assisted laparoscopic radical prostatectomy.

INDICATIONS FOR SIMPLE PROSTATECTOMY

The indications for prostatectomy, by either open or laparoscopic approach or transurethral resection, include (1) acute urinary retention; (2) recurrent or persistent UTIs; (3) significant symptoms from bladder outlet obstruction not responsive to medical therapy; (4) recurrent gross hematuria of prostatic origin; (5) pathophysiologic changes of the kidneys, ureters, or bladder secondary to prostatic obstruction; and (6) bladder calculi secondary to obstruction.

Simple prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g. If sizable bladder diverticula justify removal, suprapubic or robotic prostatectomy and diverticulectomy should be performed concurrently. If the prostatectomy is performed without the diverticulectomy, incomplete emptying of the bladder diverticulum and subsequent, persistent infection may occur. Large bladder calculi that are not amenable to easy transurethral fragmentation also may be removed during the procedure. Simple prostatectomy should be considered when a patient presents with ankylosis of the hip or other orthopedic conditions that prevent proper positioning for TURP. Also, it may be wise to perform a simple prostatectomy in men with recurrent or complex urethral conditions, such as urethral stricture or previous hypospadias repair, to avoid the urethral trauma associated with TURP. Finally, the association of an inguinal hernia with an enlarged prostate suggests a simple procedure, because the hernia may be repaired by the same lower abdominal incision (Schlegel and Walsh, 1987; Brunocilla et al, 2005) or laparoscopically/robotically (Do et al, 2011; Nakamura et al, 2011).

Contraindications to simple prostatectomy include a small fibrous gland, the presence of significant prostate cancer, and previous prostatectomy or pelvic surgery that may obliterate access to the prostate gland.

PREOPERATIVE EVALUATION

In deciding whether to perform a simple prostatectomy for symptomatic obstruction resulting from benign prostatic hyperplasia, it may be necessary to consider the upper and lower urinary tracts. Usually the patient will have already completed the International Prostate Symptom Score (IPSS) questionnaire and had a peak urinary flow rate determination. The postvoid residual urine volume

also may have been verified with abdominal ultrasonography. A cystoscopic examination is not indicated in the routine evaluation of a patient with obstructive voiding symptoms (McConnell et al, 1994). However, cystoscopy should be performed in men with hematuria, suspected urethral stricture, and bladder calculus or diverticulum. It also can be helpful in confirming the presence of a large median lobe or in assessing the length of the prostatic urethra.

Before performing a simple prostatectomy the presence of significant prostate cancer should be determined. All men should undergo a digital rectal examination and have a serum prostate-specific antigen determination. If the digital rectal examination detects induration or nodularity, or the serum prostate-specific antigen level is elevated, a transrectal ultrasound-guided biopsy of the prostate gland should be performed. Men participating in an active surveillance program for a very low-risk prostate cancer may consider a simple prostatectomy for symptomatic obstruction if he clearly understands the potential risks and benefits of the surgery. Transrectal ultrasonography, by itself, is not indicated as a first-line diagnostic test for evaluating the prostate gland to detect early, curable prostate cancer. However, it can be useful in determining prostate size.

The upper urinary tracts should be evaluated preoperatively in men with known renal disease, abnormal renal function, recurrent UTI, or hematuria. This can be accomplished by computed tomography in patients with normal renal function or by renal ultrasonography in men with compromised renal function.

Before surgery the patient should undergo a complete medical evaluation consisting of a detailed history, thorough physical examination, and appropriate laboratory assessment. Most patients will be of an age with an increased risk for cardiovascular and pulmonary disease, hypertension, diabetes mellitus, and other medical conditions. All abnormalities uncovered in this evaluation should be addressed. The patient's medications should be reviewed, and attention should be given to the agents such as aspirin and nonsteroidal anti-inflammatory agents that can contribute to perioperative bleeding. **These medications should be discontinued and therapeutic anticoagulation reversed before surgery.** In addition, a chest radiograph, electrocardiogram, routine electrolyte studies, coagulation studies, and a complete blood cell count are usually required for these patients before surgery.

Men in urinary retention should have an evaluation of renal function. If the serum creatinine value is elevated, surgery should be delayed until this parameter stabilizes. Urinalysis is performed to rule out a UTI; and, if an infection is suspected, a urine specimen should be sent for culture and sensitivity. If an infection is present, appropriate antimicrobial therapy must be instituted before surgery to prevent urinary sepsis (Serretta et al, 2002).

Historically, 3% to 10% of men undergoing an open simple prostatectomy will require one or more units of blood in the perioperative period (Serretta et al, 2002; Varkarakis et al, 2004; Zaragooshi, 2007). Thus it may be prudent to have 1 or 2 units of blood available intraoperatively for an open approach. For a robot-assisted laparoscopic simple prostatectomy approach, type and screen is sufficient.

Finally, the patient must be informed of the benefits and risks associated with simple prostatectomy and written informed consent obtained. The benefit to be achieved is improved urination. Potential risks include urinary incontinence, erectile dysfunction, retrograde ejaculation, UTI, injury to adjacent structures, bladder neck contracture, urethral stricture, and the need for a blood transfusion. Other potential untoward effects include deep vein thrombosis and pulmonary embolus. For robotic or laparoscopic approach, open conversion also should be listed as a rare, yet potential, risk.

OPERATING DAY PREPARATION

The patient is placed on a clear liquid diet for a day before the procedure and self-administers an oral bowel preparation the day

before the surgery. He is kept without oral intake after midnight and self-administers a Fleet enema the morning of surgery. The type of the anesthesia to be used and the risks associated with it are discussed and finalized with the patient and his family in conjunction with the anesthesiologist. One dose of a second-generation cephalosporin is administered before making the incision. Compression stockings and sequential compression devices in the lower extremities are used to minimize the risk for deep vein thrombosis.

SURGICAL TECHNIQUE

Anesthesia

The preferred anesthesia is general endotracheal anesthesia. Spinal or epidural anesthesia may be used only in an open approach when there is a medical or anatomic contraindication to general anesthesia or when the patient simply prefers regional anesthesia.

Open Simple Prostatectomy (Retropubic and Suprapubic Approach)

Proper Positioning of the Patient

Once anesthesia has been induced the patient is positioned on the operating table in the supine position. If a cystoscopic examination is to be performed, the patient is prepared and draped in the usual manner for a transurethral diagnostic procedure. Flexible cystoscopy, in this situation, will obviate major repositioning of the patient. After the cystoscopy the table is placed in a mild Trendelenburg position without extension.

Incision and Development of the Space of Retzius

The suprapubic area is shaved, prepared, and draped in the usual sterile manner. A 22-Fr urethral catheter with a 30-mL balloon is passed into the bladder and connected to a sterile closed drainage system, and the balloon is inflated with 30 mL of saline. A lower midline incision from the umbilicus to the pubic symphysis is made. It is deepened through the subcutaneous tissue. The linea alba is incised, allowing the rectus abdominis muscles to be separated in the midline. The transversalis fascia is incised sharply to expose the space of Retzius. At the superior aspect of the wound the posterior rectus abdominis fascia is incised above the semicircular line to the level of the umbilicus, and the peritoneum is mobilized cephalad starting at the pubic symphysis and swept anterolaterally. The pelvis is inspected for any abnormalities, and the inguinal area is examined for hernias. If a hernia is identified, it can be repaired using the preperitoneal approach (Schlegel and Walsh, 1987). A self-retaining Balfour retractor is placed in the incision and widened.

Retropubic Simple Prostatectomy

Exposure of the Prostate

A well-padded, malleable blade is connected to the Balfour retractor and used to displace the bladder posteriorly and superiorly. The anterior surface of the bladder and prostate are exposed. With the use of DeBakey forceps and Metzenbaum scissors, the preprostatic adipose tissue is gently removed to expose the superficial branch of the dorsal vein complex and the puboprostatic ligaments (Fig. 106-1).

Hemostatic Maneuvers

Before proceeding with enucleation of the prostatic adenoma it is important to achieve complete control of the dorsal vein complex as well as the lateral pedicles at the bladder neck (the main arterial blood supply to the prostate gland) (Walsh and

Oesterling, 1990). To accomplish this task the endopelvic fascia is incised laterally and the puboprostatic ligaments are partially transected, similar to the maneuver in an anatomic radical retropubic prostatectomy (Reiner and Walsh, 1979). In patients with marked prostatic enlargement this maneuver can be easier because the enlarged prostate gland protrudes out from beneath the pubic symphysis. A 3-0 Monocryl suture on a $\frac{5}{8}$ -inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate and tied (Fig. 106-2A).

Figure 106-1. Retropubic simple prostatectomy. The space of Retzius has been opened, and the periprostatic adipose tissue has been dissected free from the superficial branch of the dorsal vein complex. The endopelvic fascia is incised bilaterally (dotted lines), and the puboprostatic ligaments are transected bilaterally. (© Brady Urological Institute.)

Figure 106-2. Retropubic simple prostatectomy. A, A 2-0 chromic suture on a $\frac{5}{8}$ -inch circle-tapered needle is passed in the avascular plane between the urethra and the dorsal vein complex at the apex of the prostate. A tie is grasped and tied around the dorsal vein complex. B, With 2-0 chromic suture material on a CTX needle, a figure-of-eight suture is placed through the prostatovesicular junction just above the level of the seminal vesicles to control the main arterial blood supply to the prostate gland. When placing this suture, care must be taken to avoid entrapment of the neurovascular bundles located posteriorly and slightly laterally. (© Brady Urological Institute.)

The superficial branch of the dorsal vein at the bladder should be coagulated or ligated.

At this point attention is focused on securing the lateral pedicles at the prostatovesical junction. The 30-mL balloon of the catheter is used to identify the junction between the bladder and the prostate. The balloon is then deflated, and 2-0 chromic suture material on a large CTX needle is used to place a figure-of-eight suture deep into the prostatovesical junction at the level where the seminal vesicles approach the prostate gland bilaterally (see Fig. 106-2B). With this maneuver, the main arterial blood supply to the prostate adenoma is controlled. Having secured the dorsal vein complex earlier, the major sources of hemorrhage for this operation have been eliminated.

Enucleation of the Adenoma

With a sponge stick on the bladder neck to depress the bladder posteriorly, a No. 15 blade on a long handle is used to make a transverse capsulotomy in the prostate 1.5 to 2.0 cm distal to the bladder neck (Fig. 106-3). The superficial branch of the dorsal vein complex is transected as the transverse capsulotomy is made. It does not bleed because hemostasis of the dorsal vein complex has previously been controlled both proximally and distally. The incision is deepened to the level of the adenoma and extended sufficiently lateral in each direction to permit complete enucleation. A pair of Metzenbaum scissors is used to dissect the overlying prostatic pseudocapsule from the underlying prostatic adenoma. Once a well-defined plane is sufficiently developed, the index finger can be inserted between the prostatic adenoma and the pseudocapsule to further develop the plane laterally and posteriorly (Fig. 106-4). A pair of Metzenbaum scissors is then used to incise the anterior commissure from the bladder neck to the apex, separating the lateral lobes of the prostate anteriorly. The posterior prostatic urethra is exposed, and the index finger is inserted down to the verumontanum. The mucosa of the urethra overlying the left lateral lobe is divided sharply at the level of the apex under direct vision without injury to the external urinary sphincter. With the aid of a Babcock clamp, the left lateral lobe is removed safely. This maneuver is then repeated for the right lateral lobe. If a median lobe is present, the overlying mucosa is incised at the level of the bladder neck and this lobe is removed (Fig. 106-5). In this manner the entire prostatic adenoma is removed with preservation of a strip of posterior

prostatic urethra. Because the capsulotomy was a transverse rather than longitudinal incision there is little risk that the incision will be inadvertently extended into the sphincteric mechanism during the enucleation process, which would compromise subsequent urinary continence.

The prostatic fossa is carefully inspected to ensure that all of the adenoma has been removed and that hemostasis is complete. If hemorrhage is persistent, 4-0 chromic suture material can be used to place a figure-of-eight suture in the bladder neck at the 5- and 7-o'clock positions, as in suprapubic prostatectomy (Fig. 106-6). When placing these sutures it is necessary to visualize the ureteric orifices so that they are not incorporated. Indigo carmine dye may be given intravenously to aid in the visualization of the ureteric orifices if necessary. If the bladder neck appears obstructive at the completion of the operation, it may be appropriate to perform

Figure 106-4. Retropubic simple prostatectomy. A, With blunt dissection with the index finger, the prostatic adenoma is dissected free laterally and posteriorly. B, Metzenbaum scissors are used to divide the anterior commissure to visualize the posterior urethra and verumontanum. C, The index finger is then used to fracture the urethral mucosa at the level of the verumontanum. With this last maneuver, extreme care is taken not to injure the external sphincteric mechanism. (© Brady Urological Institute.)

Figure 106-3. Retropubic simple prostatectomy. A, With the superficial branch of the dorsal vein complex secured proximally and distally, a No. 15 blade on a long handle is used to make the transverse capsulotomy. Figure 106-5. Retropubic simple prostatectomy. A, After removal of the left lateral lobe of the prostate, the right lateral lobe is excised with the aid of a tenaculum and Metzenbaum scissors. B, Finally, the median lobe is removed under direct vision. (© Brady Urological Institute.)

a wedge resection at the 6-o'clock position and advance the bladder mucosa into the prostatic fossa.

Suprapubic Simple Prostatectomy

Exposure of the Prostate

The anterior bladder wall is identified, and two 3-0 Vicryl stitches are placed on each side of the midline below the peritoneal reflection. A vertical cystotomy is made with an electrocautery. With the use of a pair of Metzenbaum scissors, a cystotomy is then extended cephalad and caudally to within 1 cm of the bladder neck. Several pairs of stay sutures are placed using 3-0 Vicryl on each side of the midline to facilitate exposure (Fig. 106-7). A figure-of-eight suture using 3-0 Vicryl is placed and tied at the most caudal position of the cystotomy to prevent further extension of the cystotomy incision during blunt finger dissection of the adenoma. Alternatively, a transverse bladder incision can be used. After inspecting the bladder, a well-padded, malleable blade is placed in the bladder, connected

to the Balfour retractor, and used to retract the bladder cephalad. The bladder neck and prostate gland now can be visualized. A narrow Deaver retractor can be placed over the bladder neck and used to further expose the trigone. Indigo carmine dye may be given intravenously to aid in the visualization of the ureteric orifices if necessary.

Enucleation of the Adenoma

An electrocautery is used to create a circular incision in the bladder mucosa distal to the trigone (Fig. 106-8). Care is taken not to injure the ureteric orifices. With the use of a pair of Metzenbaum scissors, the plane between the prostatic adenoma and prostatic pseudocapsule is developed at the 6-o'clock position (Fig. 106-9). Once a well-established plane is created posteriorly, the prostatic adenoma is dissected circumferentially and inferiorly toward the

Figure 106-6. Hemostatic maneuver during open simple prostatectomy. After enucleation of the entire prostatic adenoma, a 0-chromic suture is used to place two figure-of-eight sutures to advance bladder mucosa into the prostatic fossa at the 5- and 7-o'clock positions at the prostatovesicular junction to ensure control of the main arterial blood supply to the prostate. (© Brady Urological Institute.)

Figure 106-7. Suprapubic simple prostatectomy. A, A lower midline incision is made from the umbilicus to the pubic symphysis. B, After developing the prevesical space, a small, longitudinal cystotomy is made with an electrocautery. (© Brady Urological Institute.)

Figure 106-9. Suprapubic simple prostatectomy. A, Starting at the bladder neck posteriorly, Metzenbaum scissors are used to develop the plane between the prostatic adenoma and the prostatic pseudocapsule (lateral view). B, Anterior view of the same maneuver. (© Brady Urological Institute.)

Figure 106-10. Suprapubic simple prostatectomy. A, Using the index finger, the prostatic adenoma is enucleated from the prostatic fossa (lateral view). B, Anterior view of the same maneuver. With extremely large prostate glands, the left, right, and median lobes should be removed separately. (© Brady Urological Institute.)

apex, using blunt dissection (Fig. 106-10). At the apex the prostatic urethra is transected using a pinch action of the two fingertips and avoiding excessive traction so as not to avulse the urethra and injure the sphincteric mechanism. At this point the prostatic adenoma, either as one unit or separate lobes, can be removed from the prostatic fossa.

Hemostatic Maneuvers

After enucleation of the adenoma the prostatic fossa is inspected for residual tissue. If found, these nodules are removed by sharp or blunt dissection. The prostatic fossa also must be examined for discrete bleeding sites that frequently can be controlled with an electrocautery or 4-0 chromic suture ligatures. In addition, a 0-chromic suture is used to place two figure-of-eight sutures to advance the bladder mucosa into the prostatic fossa at the 5-o'clock and 7-o'clock positions at the prostatovesical junction to ensure control of the main arterial blood supply to the prostate (see Fig. 106-6). With this maneuver, hemostasis is usually complete.

If hemorrhage remains pronounced despite the hemostatic sutures, a size 2 nylon purse-string suture can be placed around the vesical neck, brought out through the skin, and tied firmly, as described by Malament (1965). This maneuver closes the bladder neck and tamponades the prostatic fossa. The nylon suture is removed by cutting it at the skin and applying gentle traction on postoperative day 2 or 3. Plicating sutures can be placed transversely in the posterior prostatic pseudocapsule to prevent further bleeding, as described by O'Connor (1982).

Closure

After inspecting for complete adenoma removal and hemostasis, a 22-Fr, three-way Foley catheter with a 30-mL balloon is inserted through the anterior urethra and prostatic fossa into the bladder. Alternatively, a 22-Fr, two-way Foley catheter with a 30-mL balloon and a 20- to 24-Fr Malecot suprapubic tube are placed into the dome of the bladder. The suprapubic tube exits the bladder via a separate stab incision at the lateral aspect of the dome, avoiding the peritoneal cavity (Fig. 106-11). The suprapubic tube is secured with a 4-0 chromic purse-string suture.

In the suprapubic approach, with the urethral catheter in place, the prostatic pseudocapsule is closed (see Fig. 106-11) using 2-0 absorbable sutures. In the retropubic approach, the cystotomy incision is closed in two layers using 2-0 absorbable sutures (Fig. 106-12).

Fifty milliliters of water is then placed in the balloon to ensure the Foley catheter balloon remains in the bladder and does not

Figure 106-11. Closure during suprapubic simple prostatectomy. After placement of a urethral catheter and a Malecot suprapubic tube, the cystotomy is closed in two layers using a running 2-0 Vicryl suture, enforced by tying of multiple interrupted 3-0 Vicryl stay sutures. A closed Davol suction drain is placed on one side of the bladder and exits via a separate stab incision. (© Brady Urological Institute.)

Figure 106-12. Closure during retropubic simple prostatectomy. A, View of the prostatic fossa and posterior urethra after enucleation of all the prostatic adenoma. Note that the verumontanum and a strip of posterior urethra remain intact. B, After placement of a urethral catheter and, if needed, a Malecot suprapubic tube, the transverse capsulotomy is closed with two running 2-0 chromic sutures. The two sutures are tied first to themselves and then to each other across the midline to create a watertight closure of the prostatic pseudocapsule. (© Brady Urological Institute.)

retract into the prostatic fossa. The bladder is then irrigated with saline to ensure continued hemostasis and test the closure for leakage. A small closed-suction drain is placed via a separate stab incision lateral to the prostate and bladder on one side to prevent hematoma and urinoma formation. The pelvis is irrigated with copious amounts of normal saline solution, and the rectus fascia is reapproximated with a size 1 polydioxanone (PDS) suture on a needle in a running fashion. The skin is closed with skin staples or

4-0 absorbable suture. The drain is secured to the abdominal wall, and the urethral catheter is secured to the lower extremity.

Robot-Assisted Laparoscopic Simple Prostatectomy

Proper Positioning of the Patient

The positioning of the patient for this procedure is same as that for robot-assisted laparoscopic radical prostatectomy. After general endotracheal anesthesia has been induced, the patient is positioned on the operating table in the supine position. Both arms are padded and tucked to the side. The legs are placed in the low lithotomy position in a spreader bar. The patient is secured to the operative table at the level of the shoulders with a heavy cloth tape. The lower abdomen is shaved, prepared, and draped in the usual sterile manner. A 16-Fr urethral catheter is passed into the bladder and connected to a sterile closed drainage system. The balloon is inflated with 10 mL of saline. The operative table is placed in the maximum Trendelenburg position.

Abdominal Access, Insufflation, and Trocar Placement

The transperitoneal approach is favored over the extraperitoneal approach because of the greater working space in the setting of a massively enlarged prostatic adenoma. Intraperitoneal access is obtained with a Veress needle through umbilical puncture site. After adequate insufflation at 15 mm Hg, the peritoneal cavity is entered through a vertical supraumbilical incision using 12-mm STEP trocar, followed by confirmation of the proper placement with a robotic camera. Alternatively, the initial entrance can be achieved using the Visiport device and 0-degree lens and camera. Adhesions are lysed laparoscopically, if present. One additional 12-mm STEP trocar is placed on the right side, then three 8-mm robotic trocars are placed bilaterally (two on the left, one on the right), and then one additional 5-mm trocar is placed on the right side, all under direct laparoscopic vision. The da Vinci Robotic System is then docked between the patient's legs. Typically, three robotic instruments are used (fenestrated bipolar forceps and ProGrasp forceps on the left side and monopolar scissors on the right side).

Development of the Space of Retzius

The anterior peritoneum is taken down lateral to the medial umbilical ligaments to displace the bladder posteriorly. Applying posterior and cephalad traction on the urachus, the space of Retzius is developed using both blunt and sharp dissection. Periprostatic adipose tissue is then removed. Endopelvic fascia is taken down carefully to expose the prostatic contour. Control of the deep dorsal vein complex or prostatic lateral pedicles is not necessary.

Bladder Neck Incision

The anterior bladder neck is divided transversely using monopolar scissors until the urinary catheter is visualized. After identifying the catheter, it is grasped by an assistant or the fourth robotic arm with ProGrasp forceps and pulled anteriorly before widening the bladder neck incision. **To better visualize the intravesical component of the prostate and the trigone, the bladder neck incision in this approach should be wider and more cephalad compared to the narrow incision at the vesicoprostatic junction in a typical robot-assisted laparoscopic radical prostatectomy.** When a large median lobe is encountered, it is lifted anteriorly by the assistant or the ProGrasp forceps. Bilateral ureteric orifices are identified to avoid inadvertent injury. Indigo carmine dye may be given intravenously to aid in the visualization of the ureteric orifices if necessary.

Enucleation of the Adenoma

An electrocautery of the robotic monopolar scissors is used to create a circular incision in the bladder mucosa distal to the trigone.

Care is taken not to injure the ureteric orifices. With the use of monopolar scissors, the subcapsular plane between the prostatic adenoma and prostatic pseudocapsule is developed initially at the 6-o'clock position. **While developing the plane between the prostatic adenoma and pseudocapsule, it is crucial to have an experienced assistant or the robotic fourth arm with forceps to optimize the visualization of the dissection plane and provide traction.** Alternatively, prostatic adenoma can be manipulated during dissection using stitches placed in the lateral lobes (Sotelo et al, 2008). **Compared to the open simple prostatectomy approach, the dissection plane should be better visualized at all times during this procedure.** Once a well-established plane is created posteriorly, the prostatic adenoma is dissected circumferentially and inferiorly toward the apex, using both blunt dissection and limited electrocautery. At the apex the prostatic urethra is transected while avoiding excessive traction. At this point the prostatic adenoma, either as one unit or separate lobes, can be removed from the prostatic fossa and set aside.

Hemostatic Maneuvers

Prostatic fossa is carefully inspected, and hemostasis is achieved by limited electrocautery or suture ligatures. Posterior bladder mucosa is advanced into the posterior prostatic pseudocapsule using 3-0 polysorb sutures between the 5- and 7-o'clock position. Then, cystotomy incision is closed in two layers in a running fashion with 2-0 absorbable sutures. A 22-Fr, three-way Foley catheter is inserted. A watertight closure is confirmed using normal saline irrigation by Foley catheter. A closed-suction pelvic drain is placed through the lateral 8-mm robotic trocar site and secured to the skin.

Adenoma Extraction and Closure

Hemostasis is reconfirmed with lower insufflation pressure (<10 mm Hg). The prostatic adenoma is placed inside of the entrapment bag and extracted through extension of the supraumbilical trocar site. The rectus abdominis fascial defect of the extraction incision is closed using No. 1 PDS suture in a figure-of-eight fashion. The skin edges are reapproximated using 4-0 Biosyn subcuticular suture.

POSTOPERATIVE MANAGEMENT

In the recovery area the outputs from the pelvic drain and urethral catheter (and suprapubic tube, if present) are monitored. In addition, it is routine to verify the hematocrit. If significant hemorrhage is noted, the urethral catheter may be placed on traction so that the balloon containing 50 mL of saline can compress the bladder neck and prostatic fossa. Constant and reliable traction can be maintained by securing the catheter to the abdomen. In addition, continuous bladder irrigation can be initiated to prevent clot formation. For most patients these measures are adequate and effective. However, if excessive bleeding persists after these measures, the urethral catheter can be removed in the operating suite and a cystoscopic inspection of the prostatic fossa and bladder neck can be performed to identify and fulgurate discrete bleeding sites. If marked hemorrhage should continue to persist, re-exploration should be strongly considered.

On the evening of the day of surgery the patient is asked to perform the dorsiflexion and plantarflexion exercises while awake and perform pulmonary exercises. Effective pain management consists of intravenous opioids by a patient-controlled analgesic pump.

On the first postoperative day the patient is started on a clear liquid diet and asked to ambulate four times per day. Pulmonary exercises are continued. If the hematuria is resolved, continuous bladder irrigation can be discontinued with a urethral catheter (and suprapubic tube, if present) placed for gravity drainage. Also, the balloon in the urethral catheter is partially deflated to 30 mL of saline and residual clots are removed by irrigation.

On the second postoperative day, if urine is clear and both suprapubic tube and urethral catheter were placed intraoperatively, the urethral catheter may be removed and the suprapubic tube is clamped to allow a voiding trial. The patient is encouraged to ambulate and continue pulmonary exercises. When the patient tolerates a regular diet, oral analgesics can be given and parenteral opioids discontinued. Appropriate discharge instructions are reviewed with the patient at this time in preparation for discharge on the second day after surgery. The pelvic drain is removed if the drainage is low. Pathologic examination of the enucleated prostatic adenoma should be performed.

On discharge from the hospital the patient is encouraged to gradually increase his activity. If the patient has a clamped suprapubic tube and voids well with a minimal postvoid residual urine volume, the suprapubic tube is then removed in the clinic a week after surgery. If only the urethral catheter was used without a suprapubic tube, it is removed in the clinic a week after surgery. The patient should be able to resume full activity 4 to 6 weeks postoperatively with outpatient visits at 6 weeks and 3 months.

COMPLICATIONS

The overall rate of morbidity and mortality associated with simple prostatectomy is extremely low. Historically, excessive hemorrhage had been a major concern. But with modern surgical techniques, blood loss is now minimal and the need for a blood transfusion is uncommon (Zargooshi, 2007). In retropubic simple prostatectomy, controlling the dorsal vein complex distal to the apex of the prostate and ligating the lateral pedicles to the prostate at the prostatovesical junction markedly reduces venous and arterial bleeding, respectively. Nevertheless, it may still be prudent to have 1 to 2 units of autologous blood available at the time of open simple prostatectomy. **In laparoscopic simple prostatectomy with or without robotic assistance, pneumoperitoneum significantly decreases the perioperative hemorrhage and almost eliminates the need for blood transfusion.**

Urinary extravasation can be of concern in the immediate postoperative period; this most likely results from an incomplete closure of the prostatic capsulotomy in retropubic simple prostatectomy or the cystotomy in suprapubic simple prostatectomy and robot-assisted laparoscopic simple prostatectomy. This will usually resolve spontaneously with continued catheter drainage. The drain should be left in place until urinary extravasation ceases.

After a simple prostatectomy, urgency and urgency incontinence may be present for several weeks to several months, depending on the preoperative bladder status. If the condition is severe, the patient may be given an anticholinergic agent such as oxybutynin (Ditropan). Stress incontinence and total incontinence are rare. With a precise enucleation of the prostatic adenoma, risk for injury to the external sphincter mechanism is minimal. If stress incontinence does result after the procedure, the patient may benefit from transurethral collagen injections for a mild condition or an artificial urinary external sphincter when the situation is more severe.

Late urologic complications are not common. Acute cystitis rarely occurs as long as the patient voids to completion. Acute epididymitis can occur occasionally if infected urine refluxes into the ejaculatory ducts.

Erectile dysfunction occurs in 3% to 5% of patients undergoing a simple prostatectomy; it is more common in older men than in younger men. Retrograde ejaculation occurs in 80% to 90% of patients after surgery. Also, 2% to 5% of patients will develop a bladder neck contracture 6 to 12 weeks after an open simple prostatectomy (Tubaro et al, 2001; Varkarakis et al, 2004). If a bladder neck contracture develops, the initial management should be dilatation with urethral sounds or a direct vision incision of the bladder neck using a Collings knife to create a 22-Fr opening.

The most common nonurologic adverse effects include deep vein thrombosis, pulmonary embolus, myocardial infarction, and a cerebrovascular event. The incidence of any one of these complications

is less than 1%, and the overall mortality rate resulting from this operation should approach zero (Varkarakis et al, 2004).

SUMMARY

Simple prostatectomy, whether performed by an open retropubic or suprapubic approach or a robot-assisted laparoscopic approach, is an excellent treatment option for (1) men with symptomatic bladder outlet obstruction as a result of benign prostatic hyperplasia causing a markedly enlarged prostate gland, (2) individuals with a concomitant bladder condition, such as a bladder diverticulum or large bladder calculi, and (3) patients who cannot be placed in the dorsal lithotomy position for TURP. With improved surgical technique these procedures can be routinely performed in a precise manner with minimal hemorrhage. Efficacy, in terms of durable improvement in symptom score and peak urinary flow rate, is superior to other treatment options available for the obstructing prostate gland, including TURP. Meanwhile, complications are minimal and the length of hospitalization has been markedly reduced. For most patients, the length of hospital stay is 2 days or less. Thus, for the properly selected individual, a simple prostatectomy is a highly effective and well-tolerated operation.

KEY POINTS

- Simple prostatectomy should be considered when the obstructive tissue is estimated to weigh more than 75 g or sizable bladder diverticuli or calculi exist.
- Before performing a simple prostatectomy, the presence of significant prostate cancer should be determined.
- Potential risks of simple prostatectomy include urinary incontinence, erectile dysfunction, retrograde ejaculation, UTI, bladder neck contracture, urethral stricture, deep vein thrombosis, pulmonary embolus, and the need for blood transfusion.
- Advantages of simple prostatectomy over TURP are a lower re-treatment rate, more complete removal of the prostatic adenoma under direct vision, and no risk for TUR syndrome.
- Disadvantages of open simple prostatectomy over TURP are a lower midline incision, longer hospitalization, and increased potential for perioperative hemorrhage.
- Compared to open simple prostatectomy, robot-assisted laparoscopic simple prostatectomy can be performed with smaller incisions with shorter hospital stay and decreased risk for perioperative hemorrhage and blood transfusion.
- Two approaches to open simple prostatectomy are retropubic and suprapubic.
- Compared to retropubic approach, suprapubic prostatectomy is ideal for men with a large median lobe, clinically significant bladder diverticulum, or large bladder calculi.

EPIDEMIOLOGY

Incidence and Mortality Trends

Incidence

Prostate cancer has been the most common noncutaneous malignancy in U.S. men since 1984, now accounting for 27% of all such cancers (Siegel et al, 2014) (Fig. 107-1). Among men alive today, it is estimated that 1 in 7 (15.3%) will be diagnosed with prostate cancer and 1 in 38 (2.6%) will die from this disease (Brawley et al, 2012a). Prostate cancer incidence varies by race/ethnicity, with African-Americans experiencing 59% higher incidence rates than whites (Table 107-1) (Siegel et al, 2014). The incidence rate rose by approximately 2% per year from 1975 to the late 1980s, related in part to the incidental detection of prostate cancer associated with the use of transurethral resection of the prostate for benign prostatic hyperplasia (Potosky et al, 1990). The incidence of prostate cancer rose dramatically from 1989 to 1992 after the introduction of a prostate-specific antigen (PSA) screening test (with U.S. Food and Drug Administration [FDA] approval for early diagnosis in 1992), fell precipitously until 1995, increased slowly until 2001, and has fluctuated year to year since (see Fig. 107-1), reflecting changes in screening practices (Siegel et al, 2014). The precipitous fall in incidence between 1992 and 1995 has been attributed to the “cull effect” of identifying previously unknown cancers in the population by the use of PSA screening, followed by a return to baseline incidence rates (Stephenson et al, 1996). For 2015, an estimated 220,800 new cases of prostate cancer will be diagnosed in the United States and the age-adjusted incidence rate is 152.0 per 100,000 men per year (Siegel et al, 2014).

Mortality

Prostate cancer mortality rates in the United States rose slowly between 1973 and 1990 (Fig. 107-2). This may have resulted from a gradual increase in the number of biologically lethal cancers or a decreasing use or effectiveness of therapy during this interval. In the early 1990s an abrupt rise in mortality was observed. This increase may have been caused by an increase in attribution bias occurring when the National Center for Health Statistics made a change from manual to automated methods for assignment of cause of death (Feuer et al, 1999). Subsequent to 1991, the peak mortality year, steady declines in prostate cancer mortality were reported in both Caucasians and African-Americans at an average rate of 4.1% per year. The magnitude of this decline is nearly 2.5 times larger than the increase in mortality seen as a result of attribution bias, so it seems likely that the observed declines since 1991 are real and clinically significant (Stephenson, 2005). Prostate cancer is the second leading cause of cancer death in the United States, accounting for 10% of all such events. In 2015, an estimated

27,540 men will die from prostate cancer in the United States, for an approximate annual rate of 23.0 per 100,000 population, representing a 45% decrease from the 1991 peak (Siegel et al, 2014). Furthermore, the mortality rate for prostate cancer in Caucasians in the United States has declined to a level lower than that observed prior to the introduction of PSA-based screening in 1987 (Tarone et al, 2000). Because the natural history of progressive prostate cancer is protracted relative to other common solid malignancies, it is associated with the fewest expected years of life lost, estimated at 5.9 and 1.8 years for clinically detected and screening-detected cancers, respectively (Friman et al, 1989; Liu et al, 2013). Prostate cancer was the leading single cause of death (35%) among those diagnosed with this disease between 1973 and 2008 in the U.S. Surveillance, Epidemiology, and End Results (SEER) program, but these men were still more likely to die from other causes (Epstein et al, 2012).

The observed decline in mortality since 1991 may be due to (1) early detection and stage migration from PSA screening, (2) increased utilization and effectiveness of curative treatments, (3) changes in the attribution of cause of death, (4) improvements in therapy for advanced disease, or (5) increased risk of death from secondary causes among men receiving prostate cancer therapy (Brawley et al, 2012b). The initial decline in mortality appears to have occurred too soon after the introduction of the PSA test to be attributable to screening (Etzioni et al, 1999). One hypothesis is that it is the result of the more aggressive treatment of prostate cancer that began in the 1980s (Walsh, 2000). Indeed, the vast majority of men diagnosed with prostate cancer since 1986 have received curative-intent therapy at a rate double that observed before 1986 (Etzioni et al, 2008; Welch and Albertsen, 2009). Modeling estimates based on data from various sources suggest that screening and treatment plausibly explain 45% to 70% and 22% to 33% of the decline in prostate cancer mortality since 1991, respectively (Etzioni et al, 2008, 2012, 2013).

Racial Differences

When interpreting reported racial differences in incidence and mortality, it should be emphasized that racial/ethnic categories are defined by the U.S. Office of Management and Budget not on the basis of biology but by a social/political/cultural basis. Observed disease-related differences between groups defined in this fashion may thus not reflect underlying differences in biology. Recognizing these caveats, it is noteworthy that African-Americans and Jamaicans of African descent have the highest incidence of prostate cancer in the world (Siegel et al, 2014). Although African-Americans have experienced a greater decline in mortality than Caucasians since the early 1990s, their death rates are still 2.4 times higher.

Differences in treatment patterns by race have consistently shown that African-Americans at every stage get less aggressive

therapy regardless of age, marital status, tumor risk, and comorbidities status compared to Caucasians, even within equal-access health care systems (Klabunde et al, 1998; Hoffman et al, 2003; Shavers et al, 2004; Gross et al, 2008; Nambudiri et al, 2012; Presley et al, 2013). Even among those treated with “watchful waiting,” African-Americans receive less intensive follow-up (Shavers et al, 2004). Among men ages 67 to 84 years in the SEER-Medicare data set, the racial disparity between African-Americans and Caucasians was highest (odds ratio [OR] 0.57, 95% confidence interval [CI] 0.48 to 0.68) among those most likely to benefit (life expectancy

>10 years, Gleason score 7-10, or American Joint Committee on Cancer [AJCC] clinical stage T2b-T2c) (Presley et al, 2013). However, prostate cancer mortality among African-Americans and Caucasians is similar in equal-access health care systems (Graham-Steed et al, 2013). Many biologic, environmental, and social hypotheses have been advanced to explain these differences, including postulated differences in genetic predisposition; differences in mechanisms of tumor initiation, promotion, and/or progression; higher-fat diets, higher serum testosterone levels, or higher body mass index; structural, financial, educational, and cultural barriers to screening, early detection, and aggressive therapy; and physician bias. There are currently no data that clearly indicate if any of these hypotheses account for observed differences in incidence or mortality, and it seems likely that the source of the disparity is multifactorial.

The incidence of prostate cancer in other ethnic groups is lower than that of Caucasians and African-Americans (see Table 107-1). Interestingly, men of Asian descent living in the United States have a lower incidence compared to white Americans, but their risk is higher than that of men of similar backgrounds living in Asia (Haenszel and Kurihara, 1968; Yu et al, 1991). Likewise, Japanese immigrants have an incidence more comparable to men of similar ancestry born in the United States than to those living in Japan (Shimizu et al, 1991). These data implicate external factors (dietary, lifestyle, environmental) in the development of prostate cancer.

Global Incidence and Mortality

Prostate cancer is the second most common cancer and the sixth leading cause of cancer deaths worldwide, with an

*Per 100,000, age adjusted to the 2000 U.S. standard population. Data from Siegel R, Ma J, Zou Z, et al. Cancer statistics, 2014. CA Cancer J Clin 2014;64:9-29.

Figure 107-1. Age-adjusted cancer incidence rates for men, United States, 1975-2010. *Includes intrahepatic bile duct. (Modified from Siegel R, Ma J, Zou Z, et al. Cancer statistics, 2014. CA Cancer J Clin 2014;64:9-29.)

Figure 107-2. Age-adjusted cancer death rates for men, United States, 1975-2005. (Modified from Siegel R, Ma J, Zou Z, et al. Cancer statistics, 2014. CA Cancer J Clin 2014;64:9-29.)

estimated 899,000 cases and 258,000 deaths annually (Center et al, 2012). By 2030, these rates are anticipated to increase to 1,700,000 and 499,000 as a result of global population growth and increased life expectancy. Prostate cancer incidence rates vary by 24-fold worldwide, primarily because of differences in screening practices, although the Westernization of lifestyle has also been suggested as a possible explanation (Hsing et al, 2000). Age-standardized incidence rates per 100,000 men are highest in the highest income regions of the world, including North America (85.6), the Caribbean (71.1), Australia and New Zealand (104.2), Western Europe (93.1), and Scandinavia (73.1), and lowest in Asia (7.2) and Northern Africa (8.1). In 32 of 40 countries analyzed, increasing incidence rates over the last one to two decades were observed, and they had stabilized in 8 countries, including the United States, Canada, and Australia, where there was early adoption of PSA screening.

Prostate cancer mortality rates varied 10-fold, with the highest age-adjusted rates per 100,000 men in the Caribbean (26.3), sub-Saharan Africa (18.3 to 19.3), and South America (16.2) and the lowest in Asia (3.1). Over the last two decades, mortality rates have declined in 27 of 53 countries analyzed and have increased in 10 countries. The decreasing trends in prostate cancer mortality were mainly observed in high-income countries where PSA screening has been adopted with variable penetrance (Collin et al, 2008), such as the United States (−4.3%), Canada (−3.1%), Western Europe (−2.3 to −4%), Australia (−2.3%), and New Zealand (−2.8%). Increasing prostate cancer mortality was seen among nations of central and eastern Europe, Asia, and Africa. Prostate cancer is the most common cancer among sub-Saharan Africans, with a mortality rate more than 5 times higher than African-Americans (Gronberg, 2003; Rebbeck et al, 2013). Interestingly, both incidence (~12%) and mortality rates (1.8% to 7.8%) have increased in China and South Korea over the same period (Sim and Cheng, 2005; Center et al, 2012). Using data from population-based cancer registries, the CONCORD study found that age-standardized 5-year survival rates vary greatly, ranging from 80% or higher in the United States, Australia, and Canada to less than 40% in Denmark, Poland, and Algeria, suggesting local influences on detection and therapy (Coleman et al, 2008).

Age at Diagnosis

Prostate cancer is rarely diagnosed in men less than 50 years of age, accounting for only 2% of all cases (Jani et al, 2008). Prior to the PSA era, median age at diagnosis was 70 years, falling to 67 years over the past decade, with 63% diagnosed after age 65 (Ries et al, 2008). The incidence rate in 2005 relative to 1986 (the year before PSA screening was commercially available) was 0.56 in men age 80 years or older, 1.09 in those 70 to 79 years, 1.91 in those 60 to 69 years, 3.64 in those 50 to 59 years, and 7.23 in men less than 50 years of age (Welch and Albertsen, 2009). This reflects a shift in diagnosis to an increasingly younger population after the introduction of PSA screening, with important implications for deciding on the need for and type of therapy. The proportions of men receiving curative-intent therapy have been relatively constant since 1985 at approximately 75% among men less than 70 years of age, 50% to 60% for men 70 to 79 years, and 20% for men 80 years or older (Welch and Albertsen, 2009). Currently, the proportion of men diagnosed with prostate cancer by age is 10.1%, 30.7%, 35.3%, 19.9%, and 4.4% for men less than 55 years, 55 to 64 years, 65 to 74 years, 75 to 84 years, and greater than 84 years, respectively (Brawley et al, 2012a). While age-specific incidence rates decline after age 70, the risk of prostate cancer death increases throughout life. The average age of death from prostate cancer is 77 years and has remained stable over the last three decades (Epstein et al, 2012).

Stage at Diagnosis

In addition to changes in incidence and mortality over the last several decades, there has been a substantial shift to a more

favorable stage at presentation of newly diagnosed disease. This clinical stage migration is largely if not exclusively accounted for by PSA screening (Catalona et al, 1993; Mettlin et al, 1993). Since the introduction of PSA testing, 81% of newly diagnosed men have localized disease, whereas the incidence of metastatic disease has decreased by 75% (Newcomer et al, 1997). Nonpalpable cancers (AJCC clinical stage T1c) now account for 60% to 75% of newly diagnosed disease (Gallina et al, 2008). Clinical stage migration has also been associated with improvements in 5-year disease-specific survival, which is 99.2% overall and 28% for men with advanced disease (Siegel et al, 2014).

The use of PSA screening has also resulted in a substantial downward pathologic stage migration as evidenced by an increase in the proportion of patients with organ-confined disease (Catalona et al, 1993; Jhaveri et al, 1999), and a decrease in the proportion with seminal vesicle involvement (Gallina et al, 2008). These observations have been consistent across the United States and Europe (Gallina et al, 2008). Since 1995, however, a slowing in this trend has been observed, suggesting a diminishing effect of PSA screening on pathologic stage migration (Dong et al, 2007). The improvement in pathologic stage has been seen for clinical stages T1 to T3 tumors and all tumor grades, and has resulted in improved cancer-specific survival after therapy for patients treated late in the PSA era (Jhaveri et al, 1999).

Effect of Screening on Incidence and Mortality

The use of PSA as a screening test has had the greatest impact on the incidence and potentially the mortality of prostate cancer worldwide. Since the introduction of PSA screening, lifetime risk of prostate cancer in the United States has doubled from 7.8% to 15.3% while the risk of dying from prostate cancer has decreased from 3% to 2.6% (Siegel et al, 2014). In the Prostate Cancer Prevention Trial (PCPT), 14% of men in the placebo arm were diagnosed by annual PSA screening within 7 years of enrollment (Thompson et al, 2003), suggesting that lifetime risk with regular screening may approach 20% (Boyle and Brawley, 2009).

Recently, the results of two large randomized trials assessing the effect of PSA screening on prostate cancer mortality were published. The U.S. Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial reported on 76,685 U.S. men ages 55 to 74 years randomized between annual screening and usual care (Andriole et al, 2012). Through 13 years of follow-up the incidence of prostate cancer in the screening group was 12% higher than in the control group (108 vs. 97 per 10,000 person-years, respectively). However, there was no difference in prostate cancer mortality between the groups (3.7 vs 3.4 deaths per 10,000 person-years in the screening and control groups, respectively; hazard ratio [HR] 1.09, 95% CI 1.87 to 1.4). The trial has been criticized for high rates of prescreening (44% reported undergoing PSA testing prior to enrollment), poor compliance with prostate biopsy, and 52% contamination by ad hoc screening in the control arm. There were also identical rates of noncompliance with PSA screening (15%) in the control and screening arms (Pinsky et al, 2010). Thus the trial does not fairly compare annual screening versus none and was likely underpowered to detect meaningful differences in prostate cancer mortality between the groups. The European Randomized Study of Screening for Prostate Cancer (ERSPC) included 162,243 men between the ages of 55 and 69 years randomized between PSA screening every 4 years or no screening (Schröder et al, 2012). After a median follow-up of 11 years, men in the screening arm had a 63% (95% CI 57% to 69%) increased incidence of prostate cancer compared to controls (97 vs. 56 cancers per 10,000 person-years) and a 21% (95% CI 9% to 32%) relative reduction in death from prostate cancer (3.9 vs. 5 cancer deaths per 10,000 person-years). Extrapolating the ERSPC results to the long-term U.S. setting suggests an absolute mortality reduction up to five times greater than that observed in the ESRPC (Gulati et al, 2011).

Soon after publication of results from the PLCO trial (Andriole et al, 2009) and the ERSPC (Schröder et al, 2009), the U.S.

Preventive Services Task Force (USPSTF) in 2012 recommended against routine PSA screening in healthy men regardless of age, race, or family history. It gave PSA screening a grade “D” recommendation, meaning that there was a moderate-to-high certainty that the service has no net benefit or that the harms outweigh the benefits (Moyer and U.S. Preventive Services Task Force, 2012). The future impact of these recommendations on PSA screening practices and national prostate cancer incidence rates is uncertain. Conflicting results of the impact of the publication of findings from the PLCO trial and the ERSPC in 2009 and the earlier recommendations by the USPSTF (2008) to discontinue screening among men 75 years of age or older have been reported (Moyer and U.S. Preventive Services Task Force, 2012). No differences in self-reported PSA testing were identified among men age 75 years or older in the National Health Interview Survey between 2005 and 2010 (Prasad et al, 2012), while in the SEER-Medicare population and the Veterans Health Administration (VHA) Pacific Northwest Network, a small but statistically significant reduction in PSA testing (29.4% vs. 27.8% and 25.4% vs. 24.3%, respectively) was observed in the periods before and after the 2008 USPSTF recommendations (Zeliadt et al, 2011; Ross et al, 2012). This may have explained part of the 25% reduction in prostate cancer incidence reported in the SEER registry among men 75 years of age or older between 2007 and 2009 (Howard, 2012). Among men less than 75 years of age, the PLCO trial and ERSPC results appeared to have had minimal impact on PSA testing rates among men in a commercial insurance database (−0.7% to −1.5% change after 2009) and in the VHA (−3% change after 2009) (Zeliadt et al, 2011; Goodwin et al, 2013). In a survey of primary care practitioners in university-affiliated practice after the 2012 USPSTF recommendations, approximately half agreed with the committee’s recommendations but more than 75% reported that they would be somewhat less likely to change their PSA screening practice or that it would not change at all (Pollack et al, 2012). Even among clinicians who agreed strongly with the recommendations, only 42% stated they would no longer order a PSA test or would be much less likely to do so.

KEY POINTS: EPIDEMIOLOGY

- In the United States, prostate cancer:
 - is the most common visceral malignancy in men.
 - is the second leading cause of cancer-related deaths.
 - incidence peaked in 1992 approximately 5 years after the introduction of a PSA screening test, declined until 1995, subsequently increased at a rate similar to that observed in the pre-PSA screening era, and has fluctuated year-to-year since 2001.
 - mortality has declined since 1991 and for Caucasians is now lower than before PSA screening was introduced.
- Worldwide, prostate cancer incidence and mortality rates:
 - vary significantly between countries and regions.
 - are highest in African-American and Jamaican men.
- PSA screening has induced a significant downward migration in age and stage (both clinical and pathologic) at diagnosis.
- PSA screening may have a beneficial effect on prostate cancer mortality; however, the absolute effect is small relative to the number needed to screen and treat to cure a single individual.

RISK FACTORS

Considerable evidence suggests that both genetics and environment play a role in the origin and evolution of prostate cancer. Traditional and molecular epidemiology and newer genome-based techniques have identified a number of potential risk factors associated with the development of prostate cancer.

Familial and Germline Genetic Influences

Epidemiologic and molecular evidence suggests that prostate cancer has a strong familial component as demonstrated by epidemiologic studies and germline genetic analysis. The first reports of familial clustering were published in the mid-20th century and suggested that the risk of developing prostate cancer was higher in those with an affected first-degree relative (Woolf, 1960). Subsequent case-control and cohort studies have confirmed this observation (Eeles et al, 1997), and twin studies demonstrate that the inherited component of prostate cancer risk is over 40%, substantially higher than for other common cancers (Lichtenstein et al, 2000). Relative risk (RR) increases according to the number of affected family members, their degree of relatedness, and the age at which they were affected (Table 107-2) (Zeegers et al, 2003). About 15% of all prostate cancer is estimated to be caused by germline factors (Carter et al, 1992).

Early linkage and segregation studies identified a number of candidate prostate cancer susceptibility genes (*HPC1/RNASEL*, *HPC2/ELAC*, and *MSR1*) and loci (*PCAP/1q42.2-q43*, *CAPB/1p36*, and *Xq27-q28*). Most subsequent studies have not replicated initial findings and the role of these genes/regions is not fully established (Eeles et al, 2014), although a recent population-based study identified variant *RNASEL* alleles as one of five predictive of prostate cancer-specific mortality (Lin et al, 2011). More recently, genome-wide association studies (GWAS) have emerged as a new approach to identify alleles associated with prostate cancer risk in an unbiased fashion (i.e., without prior knowledge of their position or function). Using this technique more than 70 prostate cancer susceptibility risk alleles, many confirmed in multiple studies, have been identified on chromosomes 2, 3, 4, 5, 6, 7, 8, 10, 11, 12, 13, 17, 19, 22, and X (reviewed in Choudhury et al, 2012, and Eeles et al, 2014), which account for 25% to 30% of germline-determined risk. Studies in African-American and Japanese populations have identified additional risk alleles specific to these populations (Takata et al, 2010; Haiman et al, 2011). Reported GWAS for prostate cancer have generally included only common inherited variants (i.e., a minor allele frequency of ~5%) and in total have captured only a small fraction of the germline component of risk. As a consequence, the predictive value of most single alleles (rarely >1.5 times baseline risk) is too low to provide clinical utility as a way of identifying individual men at risk for developing prostate cancer. One approach to this challenge is to combine multiple risk alleles into a predictive model, because risk increases with the number of specific alleles carried. One such case-control study evaluated the ability of five loci (three on 8q24 and two on 17q) to predict the likelihood of prostate cancer in a population of 3161 men. The OR for prostate cancer in men who carried

TABLE 107-2 Family History and Risk of Prostate Cancer

FAMILY HISTORY	RELATIVE RISK	95% CONFIDENCE INTERVAL
None	1	
Father affected	2.17	1.90-2.49
Brother affected	3.37	2.97-3.83
First-degree family member affected, age <65 yr at diagnosis	3.34	2.64-4.23
>2 first-degree relatives affected	5.08	3.31-7.79
Second-degree relative affected	1.68	1.07-2.64

Data derived from meta-analysis assessing risk of prostate cancer for relatives of patients with prostate carcinoma (Zeegers et al, 2003).

four or five alleles was 4.47, and increased to 9.46 for those who carried all five alleles and had a positive family history (Zheng et al, 2008). While this study demonstrates the power of risk information contained within the germline, its clinical utility is limited by the fact that only a minority of the population (1.4%) carried all five risk alleles and that the model was unable to distinguish between the risk of low- versus high-grade disease. In a follow-up study, adding additional alleles only marginally improved the predictive value of the model (Sun et al, 2011).

The performance of predictive models based on germline alleles, and thus their clinical utility, may improve with the incorporation of rarer variants that confer higher risk. Several such variants with minor allele frequencies of approximately 1% have recently been described for prostate cancer. A recurrent mutation in the coding region of the *HOXB13* gene, which maps to an area of interest at 17q21-q22 identified by GWAS, was present in 1.4% of cases compared to only 0.1% of controls and was significantly more common in men with early-onset, familial prostate cancer (3.1%) than in those with late-onset, sporadic disease (0.6%) (Ewing et al, 2012). This mutation increases overall risk of disease almost five times, and more than eight times in men under age 55 years or with a family history (Witte et al, 2013). Several studies have suggested a familial coaggregation of prostate cancer with breast cancer (Thiessen, 1974; Tulinius et al, 1992; Goldgar et al, 1994), and there is clear evidence that both *BRCA1* and *BRCA2* carriers are at increased risk of prostate cancer, especially for early-onset disease. *BRCA1* has been estimated to increase risk by 1.8- to 3.5-fold and *BRCA2* from 4.6- to 8.6-fold in men under 65 (reviewed in Castro and Eeles, 2012). *BRCA*-associated cancers, especially *BRCA2*, are also more likely to present with higher grade, locally advanced, and metastatic disease and have worse cancer-specific and metastasis-free survival after prostatectomy (Castro et al, 2013).

The relative contribution of common and rare alleles to the overall germline risk of prostate cancer is illustrated in Figure 107-3. One interesting observation from GWAS is that most of the variant alleles that confer increased risk are found in noncoding regions of the genome (Choudhury et al, 2012; Eeles et al, 2014), such that

their underlying mechanism of action is not readily understood. Another common germline variation, copy number variants, has only recently begun to be studied in prostate cancer and their biologic and clinical relevance is as yet undetermined (reviewed in Barbieri et al, 2012).

Using germline information to predict the risk of developing prostate cancer for individuals or on a population basis has yet to be realized owing to the low penetrance of relevant alleles in the general population, cost, lack of ability of most alleles (alleles of *BRCA* being a notable exception) to predict for disease that is biologically significant, and lack of evidence that targeted prevention strategies or early intervention will have a meaningful impact on outcome. This body of knowledge, however, sets the stage for improved screening, prevention, and intervention strategies as the biologic function of each risk allele is understood.

KEY POINTS: FAMILIAL AND GERMLINE GENETIC INFLUENCES

- Both genetics and environment are important in the origin and evolution of prostate cancer.
- GWAS have identified multiple chromosomal loci and specific variant alleles in germline DNA that confer risk of getting prostate cancer.
- For commonly inherited variants, the predictive value is rarely more than 1.5 times baseline risk, which is too low to provide clinical utility as a way of identifying individual men at risk for developing prostate cancer. Models that include multiple risk loci or less common alleles that confer greater risk will be necessary to accomplish individual risk prediction.
- *HOXB13* and *BRCA* are two genes that substantially increase individual risk. *BRCA*-related tumors present with more aggressive clinical features.

Figure 107-3. Germline influences on susceptibility to prostate cancer. The genetic architecture of prostate cancer illustrates that susceptibility is highly likely to be due to a mixed model of common and rare genetic variants. *More common in the Scandinavian population—carrier frequency between 3.5% and 4.6% (Laitinen et al, 2013; Karlsson et al, 2014). GWAS, genome-wide association study. (From Eeles R, Goh C, Castro E, et al. The genetic epidemiology of prostate cancer and its clinical implications. *Nat Rev Urol* 2014;11:18–31.)

Inflammation and Infection

Infections cause about 16% of all cancers worldwide (de Martel et al, 2012). Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue contributes to the development of infection-associated cancers of the colon, esophagus, stomach, bladder, and liver (Coussens and Werb, 2002; De Marzo et al, 2007). Accumulating evidence suggests a similar process may underlie the development of prostate cancer, and although no specific infectious agent has been identified, inflammation caused by infection, dietary intake, or other causes likely contributes to development and progression of early-stage disease.

Inflammatory infiltrates and the histologic lesion called proliferative inflammatory atrophy (PIA) are frequent in clinical prostate specimens (De Marzo et al, 1999). PIA is a spectrum of lesions characterized by epithelial atrophy, low apoptotic index, and an increased proliferative index, usually associated with inflammatory infiltrates (Putzi and De Marzo, 2000). PIA appears to be a regenerative lesion developing as a consequence of infection or cell trauma resulting from oxidant damage, hypoxia, infection, or autoimmunity, and its hyperproliferative state may lead to cancer. PIA is often found adjacent to high-grade prostatic intraepithelial neoplasia (HGPIN) or early cancer (Putzi and De Marzo, 2000), and there is an identifiable genetic pathway between PIA, HGPIN, and cancer (Shah et al, 2001; Nakayama et al, 2003; Nelson et al, 2003).

Genetic alterations in genes that regulate the inflammatory response and mediate DNA repair, as well as histologic observations in prostate cancer, strongly suggest that compromised cellular defenses against inflammatory oxidants may initiate and/or perpetuate prostatic carcinogenesis (Klein and Silverman, 2008). Oxidative stress is mediated by reactive oxygen and nitrogen

species that bind DNA and cause mutations, and oxidant stresses from exogenous and endogenous sources are implicated in the accumulation of DNA damage that occurs with aging and subsequently leads to malignant change (Coussens and Werb, 2002).

Potential triggers for inflammation include dietary carcinogens (especially from cooked meats), estrogens, and infectious agents. Alone or together, these agents cause epithelial damage that results in an acute, chronic, and/or relapsing inflammatory response that results in epithelial cell hyperproliferation, DNA damage, accumulation of genetic defects, and ultimately precancerous lesions such as PIA and prostatic intraepithelial neoplasia (PIN) (Nelson et al, 2003) (Fig. 107-4).

There has been much interest and effort in trying to isolate and identify an infectious agent or agents that cause prostate cancer. Some, but not all, epidemiologic evidence suggests that prostate cancer may have an infectious etiology. For example, two meta-analyses examining 34 case-control studies reported statistically significant associations of prostate cancer with a history of sexually transmitted infection (STI) (RR 1.4) or prostatitis (OR 1.57) (Dennis and Dawson, 2002; Dennis et al, 2002). However, recent studies assessing the association between infection and prostate cancer have shown mixed results. In the Health Professionals Follow-up Study (Sutcliffe et al, 2006), a prospective study of 51,529 American male health professionals ages 40 to 75 years, no association was found between a self-reported history of gonorrhea or syphilis and prostate cancer, although the incidence of STI was very low in this

population. In addition, no overall correlation between prostate cancer and clinical prostatitis was found. Similarly in this cohort, no associations were observed between *Chlamydia trachomatis*, human papillomavirus (HPV)-16, HPV-18, and HPV-33 antibody seropositivity, and prostate cancer (Sutcliffe et al, 2007a). Conversely, in a small case-control study in African-American men (Sarma et al, 2006), a history of gonorrhea or prostatitis increased the odds of prostate cancer by 1.78-fold (95% CI 1.13 to 2.79) and 4.93-fold (95% CI 2.79 to 8.74), respectively, even after adjusting for potential confounders. Furthermore, men reporting 25 or more sexual partners had 2.80 times the odds of being diagnosed with cancer (95% CI 1.29 to 6.09) compared to men with 5 or fewer partners (additional data on this issue can be found in the section on Sexual Activity/Sexually Transmitted Infections).

Several studies have demonstrated evidence of viral pathogens in human prostate tissue, including HPV, human herpes simplex virus type 2, cytomegalovirus, human herpesvirus type 8, and BK virus (Strickler and Goedert, 2001; Zambrano et al, 2002; Samanta et al, 2003; Das et al, 2008). By and large these findings have not been confirmed, and a recent survey of The Cancer Genome Atlas using RNA-Seq found no evidence of DNA viral transcripts in prostate nor most other common tumors other than known virally associated cancers (Khoury et al, 2013). Initial reports of the association of the RNA virus xenotropic murine leukemia virus (MLV)-related virus (XMRV) with human prostate cancer proved unfounded (Lee et al, 2012).

In a study examining the bacterial flora of prostate cancer, Sfanos and Isaacs (2008) demonstrated the presence of 83 distinct microorganisms by sequencing bacterial 16S ribosomal DNA in core samples of 30 prostate cancers, most of which were not found by routine culture methods. The bacterium *Propionibacterium acnes* has been reported to be the predominant species in both benign and malignant prostate cancer and is associated with intraprostatic inflammation (Cohen et al, 2005; Alexeyev et al, 2006). This bacterium also induces an inflammatory response in prostate cell lines (Mak et al, 2012). Several animal models of bacterial-induced chronic prostatic inflammation induced by *P. acnes*, including a species isolated from a human prostatectomy specimen, have been established and should prove useful for testing the infection-inflammation-cancer hypothesis (Olsson et al, 2012; Shinohara et al, 2013). At present, no infectious agent has been proven to cause prostate cancer.

Figure 107-4. Effects of inflammation on early events in prostate cancer. Dietary carcinogens, activated by liver cytochrome P-450 enzymes, and oxidant carcinogens, elaborated by inflammatory cells (shown expressing the trimeric macrophage-scavenger receptor MSR1), can be detoxified in basal epithelial cells and in cells of proliferative inflammatory atrophy by the p-class glutathione S-transferase (GSTP1, shown as a dimer). Cells of prostatic intraepithelial neoplasia, devoid of GSTP1, undergo genomic damage mediated by such carcinogens. A red X indicates interception and detoxification of carcinogens. (From Nelson WG, De Marzo AM, Isaacs WB. Prostate cancer. *N Engl J Med* 2003;349:366–81.)

KEY POINTS: INFLAMMATION AND INFECTION

- Chronic inflammation leading to cellular hyperproliferation to replace damaged tissue contributes to the development of prostate cancer.
- Both genetic and histologic observations suggest that compromised cellular defenses against inflammatory oxidants are important in prostate cancer initiation and promotion.
- Inflammation may be triggered by diet, infection, estrogens, or other environmental agents.
- Some epidemiologic data suggests that a history of sexually transmitted infection or prostatitis is associated with a higher risk of prostate cancer. At present, no infectious agent has been proven to cause prostate cancer.
- Histologic evidence of inflammation, as manifested by proliferative inflammatory atrophy, is common in prostate cancer and may represent a key pathobiologic process in its development.

Molecular Epidemiology

Molecular epidemiologic approaches have identified many biomarkers of exposure measured in blood or tissue and evaluated them in relation to incidence or mortality. These biomarkers capture aspects of diet, environmental exposures, and hormonal

and other factors for which concentrations are partly genetically determined. A brief survey of major molecular epidemiologic studies relating to prostate cancer is presented.

Androgens

Androgens influence the development, maturation, and maintenance of the prostate, affecting both proliferation and differentiation of the luminal epithelium. Exposure of the prostate to androgens at key developmental times plays an important role in prostate carcinogenesis. Androgens are also important in the maintenance of established cancers, as supported by clinical experience where the majority of prostate cancers initially respond to androgen deprivation, by the central role of androgen receptor (AR) biology in castrate-resistant disease, and by results of the PCPT and Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trials, which demonstrated that inhibition of the conversion of testosterone (T) to the more potent dihydrotestosterone (DHT) by a 5 α -reductase inhibitor (5ARI) reduces the incidence of prostate cancer by 25% to 30% (Thompson et al, 2003, 2013; Andriole et al, 2010). Establishing the precise effect of androgens on risk is complicated by the complex biology of the androgen axis: (1) androgen levels are affected by both synthesis and metabolism, which are each controlled by multiple genes; (2) the biologic effects of an androgen are exerted at the cellular level by its interaction with the AR; and (3) intraprostatic and serum levels of specific androgens may differ. Polymorphisms in both synthetic and metabolic genes, including AR (Balic et al, 2002), the 5 α -reductase type 2 isoenzyme (Makridakis and Reichardt, 2004; Li et al, 2013), and genes involved in T biosynthesis (Chang et al, 2002), have been reported to affect risk. A meta-analysis of 47 published studies with 13,346 cases and 15,172 controls concluded that men with shorter CAG repeats in the AR were at higher risk for prostate cancer with an OR of 1.21 (95% CI 1.10 to 1.34), with the effect most evident in Caucasians and Asians (Sun and Lee, 2013). Polymorphisms in both the type 1 and type 2 5 α -reductase genes have been shown to affect both circulating and intraprostatic androgen levels (Lévesque et al, 2014).

High serum androgen levels have long been hypothesized to be a risk factor for prostate cancer. However, studies examining this association have been inconsistent, with only some studies finding an association between specific hormones and prostate cancer risk. A pooled analysis of 18 prospective studies assessing this association using data from 3886 men with prostate cancer and 6438 control subjects (Endogenous Hormones and Prostate Cancer Collaborative Group, 2008), failed to detect an association between the risk of prostate cancer and serum concentrations of T, calculated free T, DHT, dehydroepiandrosterone, androstenedione, androstanediol glucuronide, estradiol, or calculated free estradiol. The only positive finding was a modest inverse association between risk and serum concentration of sex hormone-binding globulin. The results suggest that one-time measurements of serum sex hormones in adulthood are not a good measure of prostate cancer risk. No studies have reported on intraprostatic androgen levels as a measure of risk in unaffected men.

Estrogens

Estrogens have both direct and indirect effects on prostatic growth and development and likely play a role in prostate cancer initiation and progression. Traditionally, estrogens have been considered protective against prostate cancer and have been used as a treatment for advanced disease. This treatment effect is primarily through a negative feedback on the hypothalamic-pituitary-gonadal axis, and also through a direct inhibitory effect of estrogens on prostate epithelial cell growth. However, there is increasing direct evidence that estrogens may act as procarcinogens in the prostate. In a novel study, isolated prostate progenitor cells from normal human prostate that were grown in three-dimensional culture to form prostatospheres expressed

estrogen receptor (ER)- α , ER- β , and estrogen-responsive G protein-coupled receptor 30 messenger RNA and protein, and grew in response to exogenous estradiol (Hu et al, 2011). When co-cultured with rat urogenital sinus mesenchyme and grown in a renal subcapsular model, subsequent exposure to T and estradiol resulted in the sequential induction of epithelial hyperplasia, PIN, and locally invasive prostate cancer in the human progenitor cells, providing direct evidence that these cells are estrogen sensitive and that estradiol is a carcinogen for human prostate epithelium. Proposed underlying mechanisms for this effect include epigenetic modifications (especially in utero), genotoxicity, induction of hyperprolactinemia, proinflammatory changes, and prostatic ER-mediated changes (reviewed in Nelles et al, 2011). The bulk of reported evidence relates to ER-mediated effects (Prins and Korach, 2008). ER- α expression, present in stromal and basal cells, is silenced in early prostate cancers and re-emerges with disease progression. Prostate epithelial ER- β may play an important role in cancer initiation, with loss of ER- β potentially contributing to disease progression in organ-confined disease (Prins and Korach, 2008). The re-emergence of ER- β expression in metastatic prostate cancer suggests a potential role in progression to castrate-resistant disease.

At a more macro level, age-related prostatic disease parallels increases in serum estrogens, and there is a low incidence of prostate cancer in cultures with diets rich in phytoestrogens (Denis et al, 1999). As for androgens, serum levels of estrogen do not correlate with prostate cancer risk (reviewed in Nelles et al, 2011), though it is clear that estradiol can be produced from T by intraprostatic aromatase (Ellem et al, 2004) and its potential biologic effects may not be evident from serum levels. Interestingly, an aromatase knockout mouse model demonstrated a lower risk of prostate cancer compared to wild-type mice after exposure to T and estrogen; the results suggest that intraprostatic estrogen production is important in prostate cancer development (Ricke et al, 2008). Similar to effects seen for androgen metabolism genes, polymorphisms in two estrogen metabolism genes, CYP1B1 and CYP19, have been observed to increase the risk of prostate cancer in a cohort of French men (Cussenot et al, 2007), and polymorphisms in CYP19A1 and UGT1A1 were associated with increased risk in the PCPT (Tang et al, 2011).

Insulin-like Growth Factor Axis

Insulin-like growth factors (IGFs) are peptide hormones that play an essential role in metabolism and body growth and exert influence on fundamental cellular processes, including proliferation, migration, and differentiation. The IGF axis consists of two ligands (IGF-I and IGF-II), two receptors (type I [IGF-IR] and type II/ mannose 6-phosphate receptor [IGF-IIR/M6P-R]), and six binding proteins (numbered IGFBP-1 to -6), the latter of which modulate IGF bioavailability (Biernacka et al, 2012). IGFs may also bind the insulin receptor, which shares many downstream targets with the IGF receptors, making the interaction of these molecules complex.

IGFs promote proliferation and inhibit apoptosis in normal prostate and tumor cells in vitro (Uzoh et al, 2011). The IGFbps can influence prostate growth independent of IGF. In particular, IGFBP-2 stimulates proliferation and IGFBP-3 promotes apoptosis and may mediate growth inhibition by 1,25-dihydroxyvitamin D (Chatterjee et al, 2004; Ingermann et al, 2010). IGFBP-3 can be cleaved by PSA, reducing its pro-apoptotic activity (Koistinen et al, 2002). In cell lines, IGF-1 can bind and activate the AR in the absence of androgen and promote androgen-independent growth (Krueckl et al, 2004).

Results of epidemiologic studies linking the IGF axis to risk have shown mostly null findings, though the data suggest a potential effect on cancer progression rather than initiation (reviewed in Uzoh et al, 2011). For example, in the PLCO trial there was no association of the IGF axis with risk of developing prostate cancer, but there was a suggestion that the ratio of IGF-1 to IGFBP-3 in obese men was predictive of disease aggressiveness (Weiss et al, 2007).

Leptin

Leptin, a peptide hormone produced by adipocytes, contributes to the control of body weight by appetite suppression and modulating energy utilization (Friedman, 2002). Obese men become leptin resistant and exhibit elevated plasma leptin (Chu et al, 2001). Epidemiologic studies assessing the association between circulating leptin concentrations and prostate cancer have yielded mixed results (Chung and Leibel, 2006). A meta-analysis concluded that a germline variant allele in the *LEP* gene is associated with a 1.2 to 1.3 times increased risk (He and Xu, 2013). There is evidence that leptin plays a role in the development of advanced disease (Ribeiro et al, 2006) by growth stimulation of the androgen-independent prostate cancer cell lines DU145 and PC-3 (Somasundar et al, 2004; Deo et al, 2008), inducing expression of vascular endothelial growth factor and basic fibroblast growth factor and stimulation of cell migration (Frankenberry et al, 2004). A variant allele in the gene for the leptin receptor, *LEPR*, was found to be the strongest predictor among five candidate genes for fatal prostate cancer in a Swedish population-based study (Lin et al, 2011).

Vitamin D, Vitamin D Receptor, and Calcium

Vitamin D (1,25-dihydroxyvitamin D₃) is an essential vitamin that is a part of the steroid hormone superfamily. Human sources include both dietary intake and sunlight exposure, which converts inactive to active vitamin D in the skin. Interest in vitamin D as a determinant of prostate cancer risk comes from epidemiologic observations (Schwartz, 2013):

1. Men living in northern latitudes with less sunlight-derived ultraviolet exposure have a higher mortality rate from prostate cancer.
2. Prostate cancer occurs more frequently in older men, in whom vitamin D deficiency is more common because of both less ultraviolet exposure and age-related declines in the hydroxylases responsible for synthesis of active vitamin D.
3. African-Americans, whose skin melanin blocks ultraviolet radiation and inhibits activation of vitamin D, have the highest worldwide incidence and mortality rates.
4. Dietary intake of dairy products rich in calcium, which depresses serum levels of vitamin D, is associated with a higher risk of prostate cancer.
5. Native Japanese, whose diet is rich in vitamin D derived from fish, have a low incidence of prostate cancer. In addition, prostate cancer cells express vitamin D receptor, and many studies have demonstrated significant biologic effects of vitamin D, including inducing cell cycle arrest and inhibiting invasion, cell migration, metastasis, and angiogenesis.

Like other steroidal regulators of prostate growth (i.e., androgens and estrogens), normal prostate epithelial cells can synthesize vitamin D, which in turn can inhibit their growth (Barreto et al, 2000). The enzyme that converts the prohormone 25-hydroxyvitamin D to the most active form of 1,25-dihydroxyvitamin D is diminished in prostate cancer, leading to a potential loss of autocrine-regulated growth inhibition (Whitlatch et al, 2002). Vitamin D receptor (VDR), which binds to 1,25-dihydroxyvitamin D from serum-derived (diet, sunlight, and paracrine sources) and autocrine sources, is also widely expressed by normal prostate epithelium (Krill et al, 2001). Polymorphisms resulting in a VDR with lower activity have been associated with increased risk for prostate cancer (John et al, 2005). Studies of plasma vitamin D levels and prostate cancer risk are mixed, with most showing no or a weak association (reviewed in Schwartz, 2013). However, there is a clear association of vitamin D levels and risk of lethal prostate cancer, as illustrated by findings in the Health Professionals Follow-up Study, where those with the highest baseline levels of plasma vitamin D had a substantially reduced risk of lethal prostate cancer, and some variant alleles in vitamin D metabolism genes and the VDR gene also modified risk (Shui et al, 2012).

A meta-analysis of 45 observational studies found null results for dairy, milk, calcium, or vitamin intake and risk of prostate

cancer (Huncharek et al, 2008). The Cancer Prevention Study II Nutrition Cohort, a prospective cohort of 65,321 men, demonstrated a modestly increased RR of 1.2 for total calcium intake (dietary and via supplements) and 1.6 for high dietary calcium intake alone (≥ 2000 vs. < 700 mg/day), but not for dairy intake (Rodriguez et al, 2003). The results suggest that very high calcium intake above daily recommendation may modestly increase risk, a finding mirrored by results of the Selenium and Vitamin E Cancer Prevention Trial (SELECT) showing that high doses of vitamin E increase risk of diagnosis (see [Vitamins and Micronutrients](#)).

KEY POINTS: MOLECULAR EPIDEMIOLOGY

- Androgen exposure of the prostate plays an important but incompletely defined role in prostate carcinogenesis.
- Long-term absence of androgen exposure to the prostate appears to protect against the development of cancer, but a dose-response relationship between androgen levels and cancer risk has not been established.
- Polymorphisms in genes encoding for the androgen receptor and various enzymes related to androgen metabolism may be important determinants of prostate cancer risk.
- Estrogen is also important in prostate cancer development, and may have varying effects depending upon local tissue activity of ER- α and ER- β . Intraprostatic estrogen production may also be important in prostate cancer development.
- The IGF axis is important in prostate cancer risk and progression.
- Vitamin D and its interaction with its receptor modulate risk and disease aggressiveness.

Other Influences

Sexual Activity/Sexually Transmitted Infections

Sexual activity has been hypothesized to expose the prostate to infectious agents, which may increase the risk of cancer by direct infection with a carcinogenic organism (akin to HPV and cervical cancer) or by initiating an inflammatory response that has known downstream carcinogenic effects. A sexually transmitted etiology for prostate cancer was first proposed in the 1950s based on an observed increased prevalence in uncircumcised men (Ravich and Ravich, 1951). A groundbreaking meta-analysis by Dennis and Dawson (2002) suggested an elevated risk of prostate cancer among men with a history of STI (especially syphilis), increasing frequency of sexual activity, and a higher number of sexual partners; however, subsequent case-control and cohort studies have not always confirmed these observations (reviewed in Sutcliffe, 2010). Prospective studies that have included measurement of serologic markers of STI have generally reported null findings. For example, in the PLCO trial a borderline increased risk of prostate cancer for a history of any STI was observed, but null results were reported for serum levels of antibodies to *C. trachomatis*, HPV-16 and -18, human herpes simplex virus type 2, cytomegalovirus, and human herpesvirus type 8 (Huang et al, 2008). A prospective cohort study of more than 68,000 men in California reported that those with a history of prostatitis or longer duration of prostatitis symptoms had an increased risk of prostate cancer compared to men with no history (RR 1.30) or shorter duration of symptoms (Cheng et al, 2010). However, this risk disappeared in those screened for cancer, and a history of STIs was not associated with risk. More recent work has identified two nontraditional infectious agents, the protozoan *Trichomonas vaginalis* and the skin bacterium *P. acnes*, as potential causes of prostatic infection and inflammation that are associated with increased risk of prostate cancer (Sutcliffe, 2010; Shinohara et al, 2013).

Studies have also suggested a protective association between prostate cancer and frequency of ejaculation, with RR ranging from

0.66 to 0.89 (Giles et al, 2003; Leitzmann et al, 2004). In the Giles and colleagues (2003) study the protective effect was seen in men who reported more than five ejaculations per week in their 20s. The large prospective cohort study by Leitzmann and coworkers (2004) demonstrated a protective effect for men reporting 21 or more ejaculations per month in their 20s and 40s, in the previous year, and as a lifetime average. The biologic basis for this effect is not known.

Vasectomy

A relationship between vasectomy and prostate cancer risk was initially suggested in a case-control study by Honda and associates (1988) and seemingly confirmed a few years later with the report of an RR of 1.6 based on two large cohort studies (Giovannucci et al, 1993a, 1993b). Not all subsequent studies have been confirmatory (reviewed in Köhler et al, 2009) and the positive studies are limited by potential confounders, including differences in vasectomy rates between cases and controls and detection bias resulting from a higher likelihood that someone undergoing vasectomy will see a urologist for screening. Two more recent case-control studies, which are notable for their careful matching of rates of vasectomy and screening, showed no increased risk for prostate cancer after vasectomy when controlling for age at diagnosis, age at vasectomy, time since vasectomy, family history of prostate cancer, tumor stage, and race (Cox et al, 2002; Holt et al, 2008). At present, the weight of evidence does not support an increased risk of prostate cancer in men who have undergone vasectomy.

Smoking

Cigarette smoke may be a risk factor for prostate cancer because it is a source of cadmium exposure, it increases circulating androgen levels, and it causes significant cellular oxidative stress. Individual case-control and cohort studies have produced conflicting results on the association of smoking and risk, but a recent meta-analysis of 24 cohort studies that included more than 26,000 patients showed a 9% to 30% increase in both incident and fatal prostate cancer associated with smoking, which was attenuated in former compared with current smokers (Huncharek et al, 2010). Some studies have suggested an association with more advanced stage at diagnosis, perhaps related to less intensive screening (Byrne et al, 2010), and there is clear evidence that current smokers are at higher risk of biochemical recurrence, metastasis, and prostate cancer-specific mortality than nonsmokers across all treatment modalities even when intensity of screening is accounted for (Kenfield et al, 2011; Moreira et al, 2014).

Diet

Descriptive epidemiologic studies of migrants, geographic variations, and temporal studies suggest that dietary factors may contribute to prostate cancer development (Bostwick et al, 2004). The incidence of latent prostate cancers is similar around the world, but the incidence of clinically manifest cancers differs, with Asians having the lowest rates of clinical disease (Center et al, 2012). Thus the most convincing evidence for the role of diet and other environmental factors in modulating prostate cancer risk comes from migration studies showing an increased incidence of prostate cancer in first-generation immigrants to the United States from Japan and China (Muir et al, 1991; Shimizu et al, 1991). These observations suggest that diet may play a role in tumor progression, allowing latent cancers to become clinically evident. A strong positive correlation exists between prostate cancer incidence and the corresponding rates of several other diet-related cancers, including breast and colon (Bostwick et al, 2004). Nonetheless, several prospective studies have failed to show an association of self-reported dietary patterns or intervention with “healthy” foods and risk of prostate cancer. In the Health Professionals Follow-up Study, consumption of a diet rich in fruits, vegetables, whole grains, fish, and poultry had a risk of prostate

cancer similar to that of a more traditional diet of meat, fat, and processed grain (Wu et al, 2006). Similarly, in the European Investigation into Cancer and Nutrition cohort, total fruit and vegetable consumption was not correlated with overall prostate cancer risk, and in a randomized intervention trial of colon polyp prevention, consumption of a low-fat and high-fruit, -vegetable, and -fiber diet over 4 years had no effect on serum PSA (Shike et al, 2002; Key et al, 2004).

Epidemiologic studies have also suggested a moderate to strong association between total and specific fats and the risk of developing prostate cancer (Chan et al, 2005). However, results from large prospective studies showed no association between dietary fat intake and prostate cancer risk (Park et al, 2007; Wallstrom et al, 2007; Crowe et al, 2008). A meta-analysis of observational studies demonstrated only a weak association between higher intake of total fat and risk of prostate cancer (RR 1.2) (Dennis et al, 2004). Observations on the association of dietary fat and risk may have alternative explanations. Diets high in meat that are sources of fat are also usually low in vegetables, which contain nutrients that may protect against prostate cancer. Furthermore, meats and dairy products contain other constituents, such as zinc and calcium, that may affect prostate cancer risk.

The nutritional complexity of the typical Western diet, the association of healthier dietary habits with healthier lifestyle choices (physical activity and smoking avoidance), and the potential interaction of specific nutrients with genetic variability among individuals are significant limitations to understanding how diet influences risk. Masko and colleagues (2013) have summarized the state of preclinical and clinical evidence that specific dietary components may exert an influence on prostate cancer risk and progression. Recent revelations about the role of intratumoral androgen in driving castrate-resistant prostate cancer have increased focus on cholesterol as a risk factor (Sharifi, 2013). Intracellular cholesterol may be carcinogenic by being a proximate steroidal precursor to both T and DHT, as well as by enhancing Akt signaling (Lee et al, 2013). Recent molecular work has demonstrated that ABCA1 (ATP-binding cassette, subfamily A, member 1), the major cellular cholesterol efflux transporter, is preferentially downregulated by promoter hypermethylation in intermediate- to high-grade prostate cancers and that its expression levels are inversely correlated with Gleason grade (Lee et al, 2013). Coupled with epidemiologic evidence that lower levels of serum cholesterol and use of cholesterol-lowering agents (statins) reduce the risk of aggressive and advanced-stage disease, loss of cholesterol homeostasis may be a contributor to prostate cancer risk and progression (Platz et al, 2006, 2009).

Obesity

Obesity as measured by body mass index (BMI) has been suggested to be a risk factor for prostate cancer because of their common occurrence in middle-aged men and clear links to colon and breast cancer risk (Giovannucci, 1995; Madigan et al, 1998). White fat in mammals serves not only as an important energy reservoir, but also as an endocrine organ, with secretion of cytokines and agents with cytokine-like activity (tumor necrosis factor- α ; interleukin-1 β , -6, -8, and -10; and transforming growth factor- β) as well as their soluble receptors (Trayhurn and Wood, 2004). Treatment of obesity through reduction in fat intake and increased exercise has been shown to reduce oxidative stress, suggesting that lifestyle modification could be important in reducing the risk of prostate cancer (Roberts et al, 2002).

Three meta-analyses of observational studies have reported a modestly increased incidence of prostate cancer in obese men, with RR ranging from 1.01 per 1-kg/m² increase in BMI to 1.03 to 1.05 per 5-kg/m² increase (Bergstrom et al, 2001; MacInnis and English, 2006; Renehan et al, 2008). Three large prospective studies, examining the association between obesity and prostate cancer risk by stage and/or grade at diagnosis, suggested that obesity was associated with a lower risk of low-grade disease, but a greater risk of high-grade disease (Gong et al, 2006;

Rodriguez et al, 2007; Wright et al, 2007). Potential explanations for the latter observation include the association of obesity with higher serum estradiol, insulin, free IGF-1, and leptin levels, and lower free T and adiponectin levels, which have also been associated with more aggressive prostate cancer (Buschemeyer and Freedland, 2007). Another possible explanation is detection bias. Higher BMI has been shown to be associated with lower serum PSA (Baillargeon et al, 2005) and larger prostates (Freedland et al, 2006), which in obese men could lead to fewer prostate biopsies and more sampling error. However, given that the association between obesity and high-grade disease was also observed in the PCPT, a study in which all men underwent biopsy, it is unlikely that detection bias is solely responsible for this finding (Gong et al, 2006).

Obesity is associated with higher rates of biochemical failure after surgery or external beam radiotherapy and a 15% to 20% increase in prostate specific-cancer mortality per 5-kg/m² increase in BMI (Masko et al, 2013). These observations likely reflect higher grade and more locally advanced disease at presentation, technical challenges in surgery and radiotherapy in obese men, and more aggressive biology driven by adipocyte-derived biologic factors. This complex interplay and specific molecular mechanisms that may underlie the biologic effects of obesity are illustrated in Figure 107-5.

Alcohol Consumption

Alcohol consumption and risk of prostate cancer is of interest because of the association of alcohol with other cancers, its effect on estrogen and T, and the high content of polyphenolic compounds with antioxidant activity in red wine (Sutcliffe et al, 2007b). Epidemiologic studies, including both case-control and cohort designs, have reported mixed results, with some suggesting increased risk, some null, and some suggesting a protective effect of alcohol use (reviewed in McGregor et al, 2013). One contemporary case-control study found lower PSA levels and an increased risk of high-grade disease at detection in heavy drinkers (Zuccolo et al, 2013).

KEY POINTS: OTHER INFLUENCES

- Smoking increases the risk of disease recurrence and death resulting from prostate cancer.
- Diet likely affects the risk of getting prostate cancer and disease progression, but the nutritional complexity of the typical Western diet, the association of healthier dietary habits with healthier lifestyle choices, and the potential interaction of specific nutrients with genetic variability among individuals are significant limitations to understanding how.
- Obesity is associated with lower serum PSA, increases the risk of getting high-grade prostate cancer, and is associated with higher treatment failure rates and disease-specific mortality.

ETIOLOGY AND MOLECULAR GENETICS

Prostate cancer is unique among solid tumors in that it exists in two forms: a histologic or clinically occult form that can be identified in approximately 30% of men older than 50 years and 60% to 70% of men older than 80 years of age, and a clinically evident form that affects approximately 1 in 6 U.S. men. Latent prostate cancer is believed to have a similar prevalence worldwide and among all ethnicities, whereas the incidence of clinical prostate cancer varies dramatically between and within different countries. For this reason, an understanding of prostate cancer etiology must encompass the steps leading to both the *initiation* of histologic cancer and *progression* to clinically evident disease. The exact molecular relationship between latent and clinical cancers is not known, and it is likely that the progression from the former to the latter is a biologic continuum with overlap in the associated molecular events. Mutations, downregulation by promoter methylation and other mechanisms, and protein modification have all been implicated in progression of prostate cancer.

Obesity and prostate cancer: weighing the evidence. *Eur Urol* 2013;63:800–9.)

The Influence of Androgens

As previously discussed, androgens play an important role in prostate carcinogenesis. The primary androgen of the prostate is DHT, irreversibly catalyzed from T by 5 α -reductase. DHT binds to intracytoplasmic ARs with much greater affinity than T, and binding of DHT to the AR enhances translocation of the steroid-receptor complex into the nucleus and activation of androgen response elements (Steers, 2001). Type 1 5 α -reductase is expressed primarily in the skin and liver and to lesser extent in prostate, while the type 2 enzyme is expressed predominantly in prostate epithelium and other genital tissues (Andriole et al, 2004a, 2004b).

Functional type 2 5 α -reductase is a prerequisite for normal development of the prostate and external genitalia in males, and insufficient exposure of the prostate to DHT appears to protect against the development of prostate cancer. Males with inherited 5 α -reductase deficiency have minuscule prostatic tissue, and biopsies demonstrate stroma but no epithelium (Imperato-McGinley and Zhu, 2002). In addition to the lack of enzyme activity, a lack of T may also protect against the development of prostate cancer, as evidenced by the atrophic prostates seen in men after surgical castration (Wilson and Roehrborn, 1999). Nonetheless, there is evidence that even hypogonadal adults can develop prostate cancer (Morgentaler and Rhoden, 2006) and that their cancers may be driven by growth pathways that are independent of androgens (though they may still act through the AR, which is known to exhibit ligand promiscuity). For example, in the placebo arm of REDUCE, there was no association of serum T or DHT levels with risk of prostate cancer or with Gleason score (Muller et al, 2012). Locally weighted scatterplot smoothing analysis, a method that allows assessment of nonlinear associations, demonstrated that cancer detection was similar among men with low compared with normal baseline T levels and that higher T levels at baseline were associated with higher prostate cancer detection only if men had low baseline T (<10 nmol/L) (OR 1.23, 95% CI 1.06 to 1.43, $P = .006$). For men with normal baseline T (≥ 10 nmol/L), higher T levels at baseline were unrelated to prostate cancer risk (Fig. 107-6A). These results suggest a saturation point for T exposure as a risk factor for prostate cancer, and that further increases in T have no effect on risk, a hypothesis that is consistent with prior observations that serum androgen levels in adulthood do not predict risk of diagnosis. The saturation model hypothesis states that changes in serum T concentrations below the point of maximal androgen-AR binding will elicit substantial changes in prostate epithelial and cancer growth but that, once maximal binding is reached, the presence of additional androgen produces little further effect (Morgentaler and Traish, 2009) (Fig. 107-6B). This model is supported by animal studies showing that intraprostatic androgen levels and prostate mass in castrated rats are extremely sensitive to serum T around near-castrate levels, but plateau above this level (Wright et al, 1999) and similar findings in intact rats showing that normal prostate growth plateaus with increasing doses of exogenous T (Banerjee et al, 1994), as well as by numerous clinical observations in humans (reviewed by Morgentaler and Traish, 2009).

In summary, exposure of the prostate to androgens before or at puberty seems to be prerequisite for later development of prostate cancer, but beyond a certain level of exposure in adulthood the risk is not linear, at least as measured by serum androgen levels.

Stem Cells

Stem cells are required for the maintenance of high cell turnover tissues where cells continually need to be replaced, and like most epithelial organs, the prostate contains stem cells capable of multilineage differentiation. The existence of prostatic stem cells is suggested by studies demonstrating the ability of prostate epithelium to regress and regenerate with repeated cycles of castration and androgen replacement (Isaacs and Coffey, 1989; Bui and

Reiter, 1998; Tsujimura et al, 2002). Supportive evidence includes observations that (1) basal and luminal cells of prostate glands have distinct phenotypes, (2) cell culture experiments demonstrate that some prostate cancer cells are self-replicating while others are not, and (3) stem cell-enriched populations of cells can produce three-dimensional structures with basal cells and fully differentiated luminal cells in nude mice (Taylor and Risbridger, 2008). In theory, stem cells have the ability to self-renew and produce differentiated progeny that populate functional prostatic cells in both the stromal and epithelial compartments.

The epithelial cell layer of the prostate, from which cancers arise, contains four distinct cell types: basal, secretory luminal, neuroendocrine, and transit-amplifying cells that have distinct morphology and molecular phenotypes (Prajapati et al, 2013) (Fig. 107-7). Luminal cells, the predominant species, are nonproliferating, androgen dependent, and terminally differentiated; they secrete both PSA and acid phosphatase. Basal cells lack AR and are therefore androgen independent. Transit-amplifying cells express both basal and luminal cell markers, and likely represent an intermediate cell type between these two. Recent studies suggest that prostate stem cells comprise about 1% of the basal cell population, based on specific marker expression and growth characteristics (Collins et al, 2001). Various genetic events in these cells can result in tumor formation from any of these cell types (Maitland and Collins, 2008) (Fig. 107-8). The biologic processes that allow stem cells to become cancers may be different than for luminal cells: the former must remain in a protective niche that allows for generation of amplifying cells even without rapid cell growth; the latter may only require changes that lead to loss of growth control. Interestingly, there is evidence that stem cells contain *TMPRSS2:ERG* fusions that are thought to be one of the earliest events in prostate cancer initiation (Polson et al, 2013), and there is evidence in a mouse bacterial prostatitis model that infection-induced inflammation accelerates disease initiation by enhancement of basal-to-luminal cell differentiation and earlier appearance of PIN (Kwon et al, 2014). Stem cell biology makes them attractive targets for both prevention and therapy.

Somatic Genetic Changes Associated with Tumor Initiation and Progression

Substantial evidence exists that prostate cancer arises and progresses by core genetic alterations that activate oncogenes and inactivate tumor suppressors. These changes result most commonly from epigenetic and structural genomic changes, including amplification, deletion, somatic copy number aberrations, and chromosomal rearrangements that result in gene fusions with novel biologic properties. Unlike in many metabolic diseases, point and missense mutations resulting in altered proteins are rare in prostate cancer, estimated to occur in only about 1% of primary tumors (Taylor et al, 2010). As noted earlier, GWAS have shown that many germline mutations occur in non-coding regions of the genome, highlighting the potential role of regulatory molecules such as microRNA (miRNA) and long noncoding RNA (lncRNA) and suggesting an even deeper biologic complexity. A plethora of studies using next-generation sequencing, microarray data, and functional studies has led to an emerging comprehensive understanding of the temporal genomic events that occur in prostate cancer development and progression to the lethal phenotype of metastatic castrate-resistant disease, and an emerging molecular classification according to whether ETS family gene fusions are present or absent (Barbieri et al, 2012; Barbieri and Tomlins, 2014) (Fig. 107-9). This section highlights the most well-characterized genomic events in early-stage prostate cancer; for a comprehensive overview the reader is referred to a number of excellent primary sources (Taylor et al, 2010; Jerónimo et al, 2011; Prensner and Chinnaiyan, 2011; Frank and Miranti, 2013; Barbieri and Tomlins, 2014).

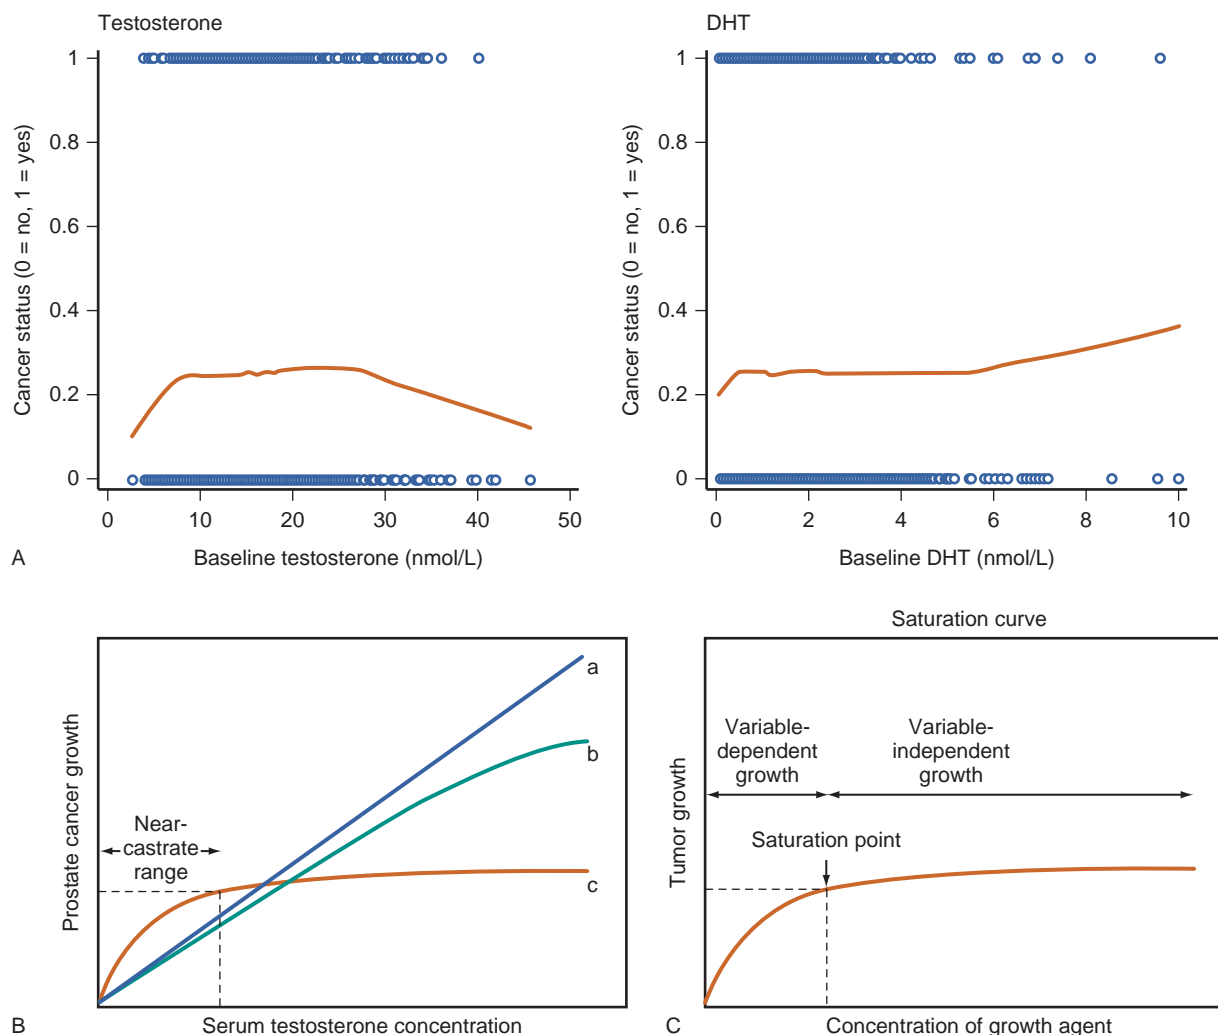

Figure 107-6. A, Locally weighted scatterplot smoothing of serum levels of testosterone and dihydrotestosterone (DHT) at baseline and final cancer status after considering all biopsies during 4 years of the REDUCE trial. The overlapping circles on the top and bottom of the chart represent each individual case. The left-hand portion of the curve for testosterone mimics that proposed in the saturation model for the effect of androgen on prostate cancer risk (see text). B, The traditional model of testosterone (T)-dependent prostate cancer growth suggested that greater serum T concentrations would lead to some degree of greater prostate cancer growth (curves a and b). The saturation model (curve c) describes a steep T-dependent curve at T concentrations at or below the near-castrate range, with a plateau representing little or no further growth above this concentration. C, The relationship between T and prostate cancer growth appears to follow a saturation curve, present in many biologic systems, in which growth corresponds with concentration of a key nutrient until a concentration is reached at which an excess of the nutrient is achieved. This type of curve is seen with hormones acting via binding to specific receptors, which have a finite number of binding sites. Once full binding is achieved (saturation), further increases in concentration of the hormone (or other nutrient) produce no further growth. (A, Modified from Muller RL, Gerber L, Moreira DM, et al. Serum testosterone and dihydrotestosterone and prostate cancer risk in the placebo arm of the Reduction by Dutasteride of Prostate Cancer Events trial. *Eur Urol* 2012;62:757–64; B and C, modified from Morgentaler A, Traish AM. Shifting the paradigm of testosterone and prostate cancer: the saturation model and the limits of androgen-dependent growth. *Eur Urol* 2009;55:310–32.)

Epigenetic Changes

Epigenetic events affect gene expression without altering the actual sequence of DNA. Known mechanisms include DNA hyper- and hypomethylation, chromatin remodeling, and miRNA and lncRNA regulation.

DNA hypermethylation generally causes gene silencing and is the most well-characterized epigenetic alteration in prostate cancer, affecting more than 50 genes across a diverse number of

basic cellular processes, including hormone response (*ESR1*, *ESR2*, and *RARB*), signal transduction (*EDNRB* and *SFRP1*), cell cycle control (*CCND2* and *SFN*), DNA repair (*GSTP1*, *GPX3*, and *GSTM1*), inflammatory response genes (*PTGS2*), tumor suppressor genes (*APC*, *RASSF1A*, *DKK3*, *CDKN2A*, *CDH1*, and *CDKN1A*), tumor invasiveness (*CD44*), and apoptosis (Li et al, 2005; Jerónimo et al, 2011). DNA hypomethylation, which usually affects areas of the genome distinct from hypermethylated regions, causes activation of oncogenes and leads to genetic instability, and has been

Figure 107-7. The epithelial and stromal cell compartments of a typical prostate gland. Each type of stromal and epithelial cell has a distinct location, morphology, and molecular phenotype. (From Prajapati A, Gupta S, Mistry B, et al. Prostate stem cells in the development of benign prostate hyperplasia and prostate cancer: emerging role and concepts. *Biomed Res Int* 2013;(2013):107954.)

Figure 107-8. Prostate carcinogenesis and tissue stem cells. Luminal cell transformation to malignancy is shown in the green cells. This requires the induction of extended life span and some de-differentiation before acquisition of mutations, while retaining the androgen receptor (AR)-positive luminal phenotype. If the origin of the tumor cells is in the basal (blue) or transit-amplifying (tan) cells, then accumulation of mutations and differentiation is required to produce AR-positive tumor cells. A stem cell origin can occur either by direct activation of a tissue stem cell or by de-differentiation of a committed basal cell into an activated stem cell. The activated stem cell can then progress/differentiate toward the final AR-positive tumor in an aberrant recapitulation of normal prostate epithelium. To achieve this requires both multiple mutagenesis and a selective process for the fittest tumor cells, by interaction with the microenvironment, resulting in the generation of further heterogeneity. (From Maitland NJ, Collins AT. Prostate cancer stem cells: a new target for therapy. *J Clin Oncol* 2008;26:2862-70.)

reported for genes associated with tumor progression (*CAGE*, *HPSE*, and *PLAU*) (Li et al, 2005). Promoter methylation of some genes is influenced by diet and age, and is frequently seen in high-grade PIN and morphologically normal prostate tissue, suggesting that these events are drivers early in the development of prostate cancer (Henrique et al, 2006). Both hypo- and hypermethylation define a field cancerization effect in normal prostate tissue, as revealed by methylation microarray analysis of tumor-associated and non-tumor-associated normal prostatic tissue (Yang et al, 2013a). Clinical studies have shown that quantitative methylation analysis of the *GSTP1*, *APC*, *PTGS2*, *RASSF1A*, *MDR1*, *CDKN2A*, and *MGMT* genes can improve sensitivity and specificity for the diagnosis of cancer (Dobosy et al, 2007). These observations have clinical utility, as demonstrated by a study showing that the

methylation status of *GSTP1*, *APC*, and *RASSF1A* on prostate needle biopsy can be used to predict the likelihood of cancer on subsequent biopsy with a negative predictive value of 90% (Stewart et al, 2013).

Chromatin remodeling and histone post-translational modifications are also important epigenetic mechanisms of gene deregulation in prostate cancer. A number of histone-modifying enzymes have been reported to be altered, the best characterized of which is the histone methyltransferase polycomb protein EZH2. EZH2 overexpression is correlated with promoter hypermethylation leading to gene silencing and is associated with higher proliferation rates and disease recurrence (van Leenders et al, 2007). Other histone modifiers, including histone deacetylators, are upregulated in prostate cancer and are targets for both prevention and therapy

using agents that can inhibit or reverse their effects. Histone acetylation also appears important in regulating AR function (Jerónimo et al, 2011).

Newly discovered forms of noncoding RNA species, including miRNA and lncRNA, affect post-transcriptional gene expression. miRNAs are typically 18 to 25 nucleotides long and act by binding to and thereby silencing messenger RNAs that have complementary sequences (Garzon et al, 2009). lncRNAs are species of greater than 200 nucleotides that regulate gene expression by a variety of mechanisms. While numerous miRNAs have been demonstrated to affect the cell cycle, intracellular signaling, DNA repair, and adhesion/migration in prostate cancer, their main effects seem to be on suppression of apoptosis and AR regulation (Catto et al, 2011). lncRNAs are emerging as molecules with fundamental biologic and clinical importance in prostate cancer. Prostate cancer gene 3 (PCA3) is a lncRNA that can be detected in urine after a digital rectal examination (DRE) and has clinical utility both in cancer detection and in deciding on the need for subsequent biopsy after an initial negative biopsy (Marks et al, 2007). The expression levels of the lncRNA SCHLAP1 (second chromosome locus associated with prostate-1) have been shown to be associated with metastasis and prostate cancer-specific mortality after radical prostatectomy (Prensner et al, 2013). Finally, a previously unknown lncRNA called prostate cancer noncoding RNA 1 (PRNCR1) has been isolated from the “gene desert” region of 8q24, the germline susceptibility locus that is most repeatedly identified in GWAS, that is overexpressed in PIN and cancer, and that causes ligand-independent activation of the AR (Chung et al, 2011; Yang et al, 2013b).

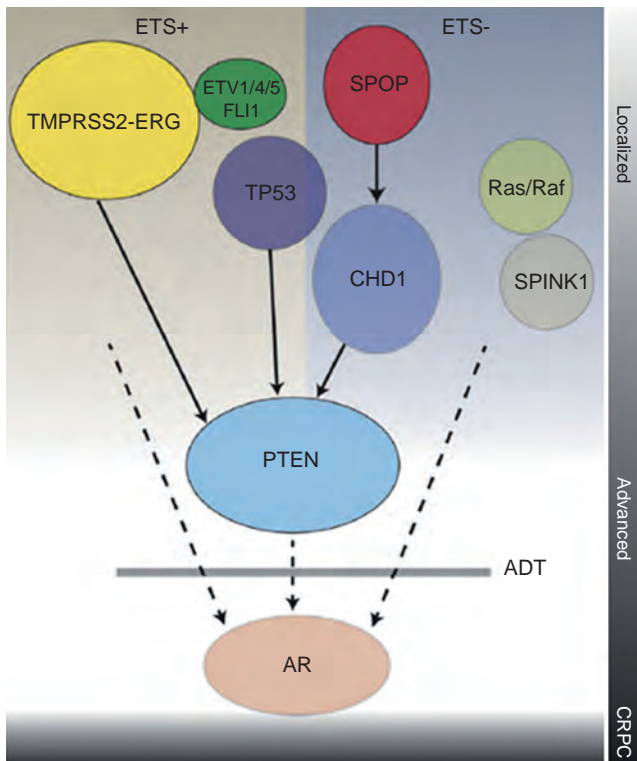

Figure 107-9. Molecular classification of prostate cancer. Genomic lesions in the time line of prostate cancer. Genes with common genomic lesions (including mutation, rearrangement, or copy number alteration) are shown. Solid arrows designate a temporal relationship between events; presumptive “early” lesions are at the top, with “later” lesions below. Tumors with ETS fusions (ETS+) are shown on the left; ETS– tumors are shown on the right. ADT, androgen deprivation therapy; CRPC, castration-resistant prostate cancer. (From Barbieri CE, Tomlins SA. The prostate cancer genome: perspectives and potential. *Urol Oncol* 2014;32:53.)

There is a complex interplay between the described epigenetic mechanisms in prostate cancer. For example, several miRNAs are known to be regulated through promoter methylation or hypomethylating enzymes. At another level of complexity, both miRNAs and EZH2 independently interact with the ETS genes fusion axis (Jerónimo et al, 2011).

Androgen Receptor

As discussed earlier, germline polymorphisms of the AR gene are linked epidemiologically to prostate cancer risk. The role of the AR is well established in the progression of castrate-resistant prostate cancer, which is characterized by AR point mutations and amplification, alternative splice mechanisms, and ligand promiscuity, which make it exquisitely sensitive to low levels of intra-tumoral androgen and/or constitutively active (Scher and Sawyers, 2005). While these lesions are absent in early-stage disease, dysregulation of the AR signaling axis may occur earlier in disease progression, involving activating mutations in FOXA1 and amplification of NCOA2 that increase androgen-dependent proliferation (Barbieri and Tomlins, 2014). The PI3K/Akt pathway has reciprocal interactions with the AR, such that inhibition of one activates the other to maintain tumor viability and suggesting that blocking both pathways simultaneously may be needed for therapeutic efficacy (Carver et al, 2011). Finally, whole-genome analysis has demonstrated that rearrangement breakpoints are more common near AR binding sites, suggesting that AR-mediated transcription brings together distant genomic loci and predisposes to genomic rearrangements (Berger et al, 2011). For example, androgen signaling promotes corecruitment of AR and topoisomerase II beta (TOP2B) to sites of TMPRSS2:ERG genomic breakpoints, triggering DNA double-strand breaks and resulting in de novo production of TMPRSS2:ERG fusion transcripts (Haffner et al, 2010). These observations suggest that AR-mediated transcriptional activity acts as an early driver of genomic rearrangements in prostate cancer, and reinforces AR-mediated transcription as a critical signaling pathway in both primary and advanced disease (Barbieri and Tomlins, 2014).

Gene Fusions

Gene fusions resulting from chromosomal translocations are the most common genetic alteration in human cancers (Futreal et al, 2004). These were previously thought to be an oncogenic mechanism exclusively limited to hematologic malignancies and sarcomas, as exemplified by the BCR:ABL1 fusion protein in chronic myeloid leukemia. In 2005, Tomlins and colleagues identified recurrent genomic rearrangements in prostate cancer that resulted in the fusion of the 5' untranslated end of TMPRSS2 (an androgen-responsive, prostate-specific, transmembrane serine protease gene) to members of the ETS family of oncogenic transcription factors (Tomlins et al, 2005). Since then other important gene fusions involving the RAF kinase family and SPINK1 have been described, highlighting the fundamental importance of this genetic mechanism in the genesis of prostate cancers (Rubin et al, 2011) (Fig. 107-10A and B). These fusions, and other gross chromosomal rearrangements, occur by a process termed *chromoplexy*, wherein translocations and deletions arise in an interdependent manner and disrupt multiple cancer genes in a coordinated fashion (Baca et al, 2013).

ETS Family Gene Fusions. The most common fusion identified in localized prostate cancer involves TMPRSS2 or other promoters (SLC45A3, HERPUD1, or NDRG) fused to ERG (ETS-related gene) in 50% to 60% of patients (Kumar-Sinha et al, 2008; Rubin et al, 2011). Gene fusions involving other members of the ETS family, most commonly ETV1 (5% to 10%), ELK4 (5%), ETV4 (2%), and ETV5 (2%), also occur. Both TMPRSS2 and SLC45A3 are androgen responsive such that fusion of either of these genes to a growth-promoting gene of the normally androgen-indifferent ETS family brings a powerful signal for cellular growth under

androgen control. These fusions are not observed in benign prostate tissue or PIA, but are present in prostate stem cells, high-grade PIN, and early-stage, low-grade prostate cancer, suggesting that this is an early and seminal event in prostate tumorigenesis that may drive the transition from PIN to cancer (Rubin et al, 2011; Polson et al, 2013). Recent data from animal models suggest that defects in the PTEN/PI3K/Akt pathway in the presence of *TMPRSS2:ERG* fusions drive early tumor progression, the former stimulating proliferation and the latter cell migration that together may result in a more aggressive phenotype (Carver et al, 2009). However, there are mixed data on whether the presence of *TMPRSS2:ERG* fusions affect prognosis (reviewed in Rubin et al, 2011), such that tumor aggressiveness may not be determined by the fusion alone but by the presence of the fusion and which other specific genetic defects are present in an individual tumor.

The high specificity of the *TMPRSS2:ERG* fusion for cancer makes it an attractive target for clinical use. Fusion transcripts can be detected in the urine and clinical evidence suggests that, when combined with an assay for *PCA3*, its use can improve the detection of cancer in screened populations over PSA alone (Tomlins et al, 2011). Some data suggest that quantification of the *TMPRSS2:ERG* fusion in urine can predict both tumor volume and tumor aggressiveness, perhaps making it useful for selecting appropriate candidates for active surveillance (Lin et al, 2013). It has been observed that not all tumor foci within a prostate harbor ETS fusions, so that a positive urine test for *TMPRSS2:ERG* fusion in the face of a negative biopsy would suggest that cancer was missed as a result of sampling error, and that additional evaluation with magnetic resonance imaging or repeat biopsy is indicated. The presence of gene fusions that occur only in cancer also makes them targets for novel therapies (see Fig. 107-10A).

Other Gene Fusions. As noted, prostate cancers also are rarely observed to contain fusions involving *SPINK1* and *RAF* kinases. *SPINK1* fusions occur in about 10% to 15% of cancers, exclusively in ETS fusion-negative tumors, and in cell lines seem to drive tumor invasion (Tomlins et al, 2008). Fusions involving *RAF* kinases are even more rare and also define another ETS fusion-negative phenotype that is associated with aggressive cancers (Palanisamy et al, 2010). Both examples likely represent alternative growth pathways for ETS fusion-negative tumors and may represent distinct phenotypes (see Fig. 107-9).

NKX3-1

NKX3-1 is an androgen-regulated and prostate-specific gene belonging to the homeobox gene family that protects against DNA damage

and promotes DNA repair. Decreased expression of this gene by mutation, promoter methylation, or post-transcriptional events leads to epithelial DNA damage and increased rates of proliferation. Loss of *NKX3-1* function is seen in areas of bacterial-induced prostatitis in a mouse model (Khalili et al, 2010) and in human PIA, PIN, and most prostate cancers and is likely an early event in prostate tumorigenesis (Bethel et al, 2006; Bowen et al, 2013).

Phosphatidylinositol 3-Kinase (PI3K) Pathway

PI3K is one of the most frequently dysregulated signaling pathways in human cancer and plays an important role in both early- and late-stage prostate cancer, with alterations occurring in 25% to 70% of tumors (Barbieri et al, 2013). The pathway may be activated by several mechanisms and results in alterations in proliferation, cell survival, and invasion. Loss-of-function mutations in *PTEN* and *PHLPP1* and amplification and gain-of-function mutations in *PIK3CA* are the commonest mechanisms of PI3K activation in prostate cancer. *PTEN* deletions occur in about 40% of primary tumors, are a central mechanism of tumor progression, and are associated with the risk of advanced disease and poor prognosis (Frank et al, 2013).

SPOP Mutations

Mutations in *SPOP*, which encodes a subunit of a ubiquitin ligase, are the most common point mutations in primary prostate cancer, with a frequency of 6% to 15% (Barbieri and Tomlins, 2014). Tumors with *SPOP* mutations have several unique molecular characteristics. They do not occur in ETS fusion-positive tumors or in those with p53 abnormalities, usually lack defects in the PI3K pathway, and typically contain deletions in the *CHD1* gene and at 6q21. *CHD1* encodes a DNA helicase binding protein that regulates transcription epigenetically by chromatin remodeling, and *CHD1*-negative tumors have an increased frequency of chromosomal rearrangements. Like *RAF* kinase- and *SPINK1*-associated tumors, *SPOP* and *CHD1* mutations may define a distinct molecular subtype of prostate cancer (see Fig. 107-9).

TP53

The well-known tumor suppressor gene *TP53* activates the transcription of genes involved in cell cycle arrest, DNA repair, and apoptosis, and its dysregulation results in improved cell survival, genomic instability, and proliferation. About 25% to 30% of clinically localized cancers have lesions in this gene. Whole-genome analysis

Continued

B

Figure 107-10, cont'd B, Prostate cancer gene fusion classification. This schematic highlights gene fusions categorized into ETS rearrangements, RAF kinase gene fusions, and *SPINK1*-positive, ETS rearrangement-negative prostate cancers. The percentages highlight the estimated frequency of each gene fusion on the basis of published screens. (A, Modified from Muller RL, Gerber L, Moreira DM, et al. Serum testosterone and dihydrotestosterone and prostate cancer risk in the placebo arm of the Reduction by Dutasteride of Prostate Cancer Events trial. *Eur Urol* 2012;62:757-64; B, from Rubin MA, Maher CA, Chinnaiyan AM. Common gene rearrangements in prostate cancer. *J Clin Oncol* 2011;29:3659-68.)

suggests that in some cases disruption of *TP53* occurs early in tumorigenesis, following deletion of *NKX3-1* or *FOXP1* and fusion of *TPMRSS2* and *ERG* (Baca et al, 2013).

An Integrated Model of Prostate Cancer Tumorigenesis

A comprehensive, integrated model of the genetic and environmental events that underlie the genesis and progression of prostate cancer from germline susceptibility to castrate-resistant metastatic disease is now emerging (see Fig. 107-9). Early events in genetically susceptible men include environmental insults such as diet and infection that result in inflammatory insults to DNA integrity in prostate epithelium. Early genetic events that fuel the progression of precursor lesions to early cancers include *NKX3-1* deletion and ETS fusion or, alternatively, mutations in *SPOP* and *FOXA1* in ETS-negative tumors. Mutations in classic tumor suppressors such as *TP53* follow, leading to inactivation of the PI3K/PTEN/Akt pathway and disease progression, culminating in the multifaceted dysregulation of AR function and signaling that leads to lethal disease. While many gaps in understanding this process still exist, we are on the threshold of having a detailed molecular map with temporal sequencing that will allow advances in the most important clinical challenges facing the field: improved identification of those at risk of disease development who will be the best candidates for chemoprevention, improved identification of those with indolent tumors who can avoid or delay initial therapy, biologic measures of disease progression that identify those who need therapy, and targeted molecular therapy for those with progressive disease.

KEY POINTS: ETIOLOGY AND MOLECULAR GENETICS

- The primary androgen of the prostate is DHT, formed by the action of 5 α -reductase on testosterone. Functional type 2 5 α -reductase is a prerequisite for normal development of the prostate and external genitalia in males, and insufficient exposure of the prostate to DHT appears to protect against the development of prostate cancer.
- Prostatic stem cells are precursors with multilineage differentiation potential that give rise to all four cell types of prostatic epithelium. Stem cells can repopulate damaged or post-therapy depleted cancer epithelial cells and may give rise to prostate cancer directly.
- Prostate cancer arises and progresses by core genetic alterations that activate oncogenes and inactivate tumor suppressors. These changes result most commonly from epigenetic and structural genomic changes, including amplification, deletion, somatic copy number aberrations, and chromosomal rearrangements that result in gene fusions with novel biologic properties.
- Epigenetic regulation of gene expression by promoter methylation, hypomethylation, and chromatin remodeling is important in prostate cancer development and progression.
- miRNA and lncRNA are also important epigenetic mechanisms of modulating tumor growth and progression.
- The AR plays a central role in prostate cancer development and progression.
- Gene fusions, especially those involving androgen-sensitive promoters such as *TPMRSS2* and the ETS family of oncogenic transcription factors, are fundamental drivers of prostate cancer initiation and progression.
- Somatic mutations in a variety of genes with diverse biologic functions have been implicated in prostate cancer development and progression.
- Mutations, amplification, and ligand promiscuity of the AR are important determinants of progressive castrate-resistant prostate cancer.

CHEMOPREVENTION

Rationale

The ubiquity and mortality of prostate cancer make it an attractive target for chemoprevention, defined as the use of natural or synthetic agents that reverse, suppress, or prevent the carcinogenic process, thereby preventing the development of clinically evident cancer. The goal of chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality. Primary chemoprevention targets the general population of healthy individuals at risk to prevent the development of prostate cancer. Secondary prevention strategies target individuals with premalignant lesions (such as HGPIN) with the goal of preventing progression to frank cancer. Tertiary prevention aims to prevent the development of a second primary cancer in an affected individual. Numerous epidemiologic observations suggest associations between dietary and lifestyle factors and the risk for developing prostate cancer. The clinical rationale for chemoprevention is based on the fact that the risk factors for prostate cancer (age, ethnicity, and family history) are not modifiable (with the exception of PSA screening). The biologic rationale is that premalignant changes appear as long as 20 to 30 years before the appearance of cancer (Nelson et al, 2003; Umar et al, 2012), providing an opportunity to intervene before a malignancy is established by using lifestyle changes (dietary alterations, smoking cessation, exercise) or by chemoprevention. The challenge of chemoprevention is finding an effective intervention that has acceptable toxicity, as well as identifying a population of individuals at sufficiently increased risk for developing prostate cancer for whom chemoprevention is appropriate and cost-effective (Fig. 107-11).

One impetus for primary prevention is the limitations of screening that were highlighted by the PLCO trial and the ERSPC (discussed previously) that show no (PLCO) or modest (ERSPC) reductions in prostate cancer-related mortality but a substantial risk of overdiagnosis (defined as a cancer that would have remained undetected over a man's lifetime in the absence of screening). Although the safety and feasibility of expectant management have been well demonstrated, in the United States a diagnosis of prostate cancer in an individual generally leads to curative-intent therapy (Welch and Albertsen, 2009) since active surveillance has not been widely embraced because of concerns that clinical staging and grading will underestimate the threat posed by cancers (Carter et al, 2003; Harlan et al, 2003; Barocas et al, 2008). A recent population-based study showed that more than 70% of men ages

Figure 107-11. Framework for the prevention of prostate cancer based on a man's risk of developing the disease and the intensity of the preventive strategy. PSA, prostate-specific antigen. (Modified from Stephenson AJ, Abouassaly R, Klein EA. Chemoprevention of prostate cancer. *Urol Clin North Am* 2010;37:11–21.)

65 to 80 years with low- and intermediate-risk disease received some form of therapy after diagnosis (Wong et al, 2006). Given the protracted natural history of screening-detected cancers, it is unlikely that many of these men benefited from treatment in terms of preventing metastasis or death, though therapy is associated with significant impacts on quality of life and low but defined rates of treatment-related mortality. An effective primary prevention strategy would spare many men the burden of diagnosis and cure and reduce overdiagnosis associated with screening. When combined with aggressive early detection and treatment, chemoprevention also has the potential to reduce the mortality from prostate cancer, which remains the second leading cause of cancer deaths among men in the United States. A number of large, controlled, randomized trials that tested the ability of various agents to prevent prostate cancer have been reported in recent years and are reviewed here.

Pharmacologic Agents

5 α -Reductase Inhibitors

Prostate Cancer Prevention Trial. The PCPT was the first large-scale primary chemoprevention trial in men at risk for prostate cancer (Thompson et al, 2003). The study randomized 18,882 men age 55 years or older with a normal DRE and a PSA level of 3.0 ng/mL or less to finasteride 5 mg or placebo daily for 7 years. The rationale for finasteride (a selective type 2 5ARI) as a chemopreventive agent was based on the absence of prostate cancer in men with congenital deficiency of 5 α -reductase (the enzyme that converts T to DHT) and the critical role of androgens in the development of prostate cancer. Biopsy was recommended at the end of the study for all participants or “for cause” in men who had a PSA level of 4 ng/mL or greater (adjusted for the effect of finasteride) or an abnormal DRE. The primary end point was the prevalence of prostate cancer during the 7 years of the study. Ultimately, 9060 participants (48%) were evaluable for the primary end point.

The main finding of the PCPT was a 25% (95% CI 19% to 31%) reduction in the period prevalence of prostate cancer in men taking finasteride (18.4%) compared to placebo (24.4%). The relative benefit of finasteride versus placebo in reducing the risk of prostate cancer was apparent across all groups as defined by age, ethnicity, family history of prostate cancer, and PSA level at study entry, with HRs between 0.66 and 0.81. The risk reduction in the finasteride arm was seen in both clinically apparent tumors (those diagnosed “for cause” because of an elevated PSA or abnormal DRE) and end-of-study biopsies (men with PSA <4.0 ng/mL and normal DRE at study termination). Finasteride also reduced the risk of HGPIN (without associated prostate cancer) compared to placebo (HR 0.85, 95% CI 0.73 to 0.99, $P = .04$) (Thompson et al, 2007a). However, a significant increase in the prevalence of biopsy Gleason score 7-10 cancers was observed in men receiving finasteride (280 [37%]) compared to placebo (237 [22%]), particularly for biopsy Gleason score 8-10 cancers (90 [12%] in the finasteride arm vs. 53 [5%] in the placebo arm).

A number of relevant observations can be made about the results of the trial. Most surprising was the 24.4% prevalence of prostate cancer in the placebo arm, four times higher than the 6% assumed for the trial design. This discrepancy can be explained by the fact that the 6% assumption was based on SEER incidence estimates, which are derived from clinically evident cases, and not on the prevalence in men undergoing biopsy with PSA less than 4 ng/mL and normal DRE. The incidence of clinically evident cancers detected “for cause” by elevations in PSA or abnormal PSA was 7.2% at 7 years, similar to the cancer incidence in the screening arms of the ERSPC (8.2%) and the PLCO trial (7.4%) (Andriole et al, 2009; Schröder et al, 2009). Another observation was a marked effect of finasteride on the prevalence of biopsy Gleason score 2-6 tumors, no effect on the prevalence of biopsy Gleason score 7 tumors, and an increase in the prevalence of biopsy Gleason score 8-10 tumors. The higher incidence of biopsy Gleason score 8-10 tumors was restricted to those men undergoing “for-cause” biopsy, though this is partly explained by the low prevalence

of these high-grade cancers in men with PSA less than 4.0 ng/mL and normal DRE (20 of 3652 in the finasteride arm vs. 8 of 3820 in the placebo arm).

Secondary analyses of the PCPT have demonstrated an overall improved sensitivity of DRE as well as a higher accuracy of PSA for the diagnosis of prostate cancer in the finasteride arm (Thompson et al, 2006, 2007b). Finasteride-treated glands were also 28% smaller on average compared to those in the placebo arm, and data suggest that having a smaller prostate enhances the detection of cancer and proportionately more diagnosed cancers are high grade (Kulkarni et al, 2006). These effects of finasteride on the detection of prostate cancer should bias the PCPT in favor of the placebo arm and lead to a greater detection of all grades of prostate cancer with finasteride, further strengthening the results of the trial.

There are two areas of continued debate over the results of the PCPT. The first is that critics argue that finasteride prevents insignificant cancers and does little to prevent “potentially lethal” cancers. This criticism is based on the fact that the incidence of cancers in the control arm (24.4%) was significantly higher than a man's lifetime risk of developing prostate cancer (18%) and 4 times higher than the cancer incidence in screening trials over a similar time period. Finasteride also reduced the prevalence of low-grade cancers and did not appear to reduce the risk of high-grade cancers. However, in a secondary analysis of 93.4% of biopsy specimens that were subject to central pathology review, the rate of insignificant cancers as defined by the Epstein criteria (Epstein et al, 1994) among the biopsy Gleason 2-6 cancers detected in the finasteride (38%) and placebo (36%) arms was not significantly different (Lucia et al, 2008). Viewed in the context of “clinical relevance” as defined by current urologic practice, preventing biopsy Gleason 2-6 cancers by finasteride also prevents the anxiety, cost, and morbidity associated with their treatment. From a public health perspective, preventing the “burden of cure” in newly diagnosed patients should be added as a positive to the 25% reduction in risk of diagnosis and significant reduction in urinary symptoms associated with finasteride use.

The second question still under debate is whether finasteride induces the development of high-grade or aggressive cancers. Androgen deprivation therapy is known to change the appearance of prostatic epithelium in a way that could bias interpretation (Civantos et al, 1996). Thus the apparent increase in high-grade cancers in men treated with finasteride may be an artifact of these morphologic changes. However, when this was examined in the PCPT, there appeared to be no morphologic effect of finasteride on prostate cancer grading when specimens were reviewed by a panel of expert pathologists blinded to treatment arm (Lucia et al, 2008). Another potential explanation for the observed increase in high-grade tumors in the finasteride group is ascertainment bias. As stated above, finasteride has been shown to increase the sensitivity of PSA and DRE as well as decrease prostate volume by 28%, leading to a higher probability of finding the high-grade component of cancer (among men with Gleason 7-10 cancer) on biopsy. Indeed, the rate of upgrading from biopsy Gleason score 2-6 to pathologic Gleason score 7-10 among men treated by radical prostatectomy was higher in the placebo arm compared to the finasteride arm (Lucia et al, 2008).

If finasteride induces high-grade cancers, one would expect a higher proportion of cancers with adverse features by biopsy criteria or at radical prostatectomy in the finasteride arm. Among Gleason 7-10 cancers, use of finasteride was associated with more favorable features of tumor extent on biopsy specimens compared to placebo, including percent of positive cores (34% vs. 38%, $P = .016$), aggregate linear tumor length (7.6 vs. 9.2 mm, $P = .13$), bilaterality (23% vs. 31%, $P = .046$), and perineural invasion (14% vs. 20%, $P = .07$) (Lucia et al, 2007, 2008). Among the 528 men who were treated by radical prostatectomy, no significant difference in the rate of extraprostatic extension, seminal vesicle invasion, or lymph node metastasis was observed between the two arms and there were fewer pathologic Gleason 7-10 cancers among men treated with finasteride versus placebo (89 vs. 105).

In a secondary analysis of the PCPT that adjusted for the effects of finasteride on the detection of prostate cancer, the adjusted prostate cancer rates were estimated to be 21.1% for the placebo group and 14.7% in the finasteride group, a 30% risk reduction for all cancers (HR 0.70, 95% CI 0.64 to 0.76) and a non-statistically significant 14% increase in high-grade cancer (Redman et al, 2008). Accounting for the increased probability of upgrading to pathologic Gleason 7-10 cancer at radical prostatectomy among men with biopsy Gleason 2-6 cancers in the placebo arm, the investigators estimated the rate of true high-grade cancer to be 6% in the finasteride arm and 8.2% in the placebo arm, representing a 27% RR reduction in the rate of true high-grade cancers in men treated with finasteride (HR 0.73, 95% CI 0.56 to 0.96). Using different methodology in an independent analysis, Pinsky and colleagues (2008) concurred that the rate of true high-grade disease may have been lower in the finasteride group compared with the placebo group.

In a long-term follow-up study of all 18,880 men enrolled in the PCPT, some of whom had survival information out to 18 years, no significant differences between treatment groups were observed for overall survival at 15 years (78% vs. 78.2%; unadjusted HR 1.02, 95% CI 0.97 to 1.08, $P = .5$) or among 2401 men with prostate cancer at 10 years (79.3% vs. 79.5%; adjusted HR 1.01, 95% CI 0.85 to 1.2, $P = .9$) (Thompson et al, 2013) (Fig. 107-12). Considering all men enrolled in the PCPT and with additional follow-up, prostate cancer was detected in 989 of 9423 (10.5%) in the finasteride arm compared to 1412 of 9457 (14.9%) in the placebo arm, translating into a 30% reduction in the detection of prostate cancer (HR 0.7, 95% CI 0.65 to 0.76, $P < .001$)

with a nonsignificant increase in Gleason 7-10 cancers (HR 1.17, 95% CI 1.00 to 1.37, $P = .05$). Analysis of cancer-specific mortality was limited because of the small number of men in whom cause of death was ascertained. The absence of important survival differences between treatment arms (and among those with cancer) suggests that the apparent higher incidence of higher-grade cancers in men treated with finasteride does not translate to important survival differences at 15 years. While finasteride did not appear to reduce overall mortality, it was associated with a 43% reduction in the risk of low-grade cancers. Using survival data from the PLCO trial to project prostate cancer mortality from incidence patterns, Pinsky and colleagues (2013) estimated that use of 5ARIs had no impact on prostate cancer mortality based on the PCPT data using unadjusted (HR 1.02, 95% CI 0.9 to 1.2) and adjusted (HR 0.9, 95% CI 0.8 to 1.1) analyses for the effects of 5ARIs on cancer detection. Together, these studies suggest that the apparent increase in high-grade cancers with the use of 5ARIs does not translate into impacts on survival or mortality from prostate cancer.

In addition to the prevention of prostate cancer, 5ARIs have other benefits that need to be considered. As mentioned earlier, finasteride improves the sensitivity of PSA and DRE for prostate cancer detection (Thompson et al, 2006, 2007b). Furthermore, finasteride reduced the risk of prostatitis, acute urinary retention, and the need for surgical intervention. On the other hand, adverse effects more common with finasteride than placebo include impaired sexual or erectile function and endocrine effects. Pooled data from randomized trials indicate absolute differences of 2% (95% CI 1% to 2%) for gynecomastia, 3% (95% CI 1% to 6%) for

Figure 107-12. Overall survival of men with prostate cancer, according to cancer grade, in the Prostate Cancer Prevention Trial. (Modified from Thompson IM Jr, Goodman PJ, Tangen CM, et al. Long-term survival of participants in the prostate cancer prevention trial. *N Engl J Med* 2013;369:603-10.)

decreased libido, 4% (95% CI 1% to 8%) for erectile dysfunction, and 4% (95% CI 8% to 17%) for reduced volume of ejaculate (Wilt et al, 2008). Sexual dysfunction was also assessed in the PCPT participants during the 7-year trial period using the Sexual Activity Scale. Compared to baseline scores, over the course of 7 years finasteride was associated with a slight increase in sexual dysfunction relative to placebo, equivalent to about half the effect of being 6.5 years older at randomization (Moinpour et al, 2007).

Reduction by Dutasteride of Prostate Cancer Events (REDUCE)

Trial. REDUCE is another large-scale, randomized, placebo-controlled primary chemoprevention trial using a different 5ARI called dutasteride, which is an inhibitor of both type 1 and type 2 isoforms of 5 α -reductase. Dutasteride has been shown to reduce the risk of prostate cancer in men treated for lower urinary tract symptoms related to benign prostatic hyperplasia (BPH) compared to placebo (Andriole et al, 2004b). Eligibility for REDUCE included men with a prior negative prostate biopsy (6 to 12 cores) within 6 months of enrollment who were 50 to 75 years of age and had baseline PSA of 2.5 to 10 ng/mL and prostate volume of 80 mL or less. The primary end point of REDUCE was the prevalence of cancer on study-mandated 10-core prostate biopsies performed at 2 and 4 years after randomization.

REDUCE accrued 8231 men, of whom 6726 (82.6%) underwent at least one biopsy and 1516 (22.5%) were diagnosed with prostate cancer. Dutasteride reduced the risk of prostate cancer over 4 years by 23% (858 in the placebo arm vs. 659 in the dutasteride arm, $P < .001$) and showed similar reductions in years 1 and 2 and years 3 and 4 (Andriole et al, 2010). There was no significant difference between groups in terms of cancer reduction on protocol-independent ("for-cause") biopsies (17% in both arms). As with finasteride in the PCPT, the benefit of dutasteride versus placebo in prostate cancer risk was apparent across all subgroups, including age, family history, and PSA level at study entry (RR reduction 22% to 32%). While there was no difference in the detection of Gleason 7-10 cancers throughout the study ($P = .8$), including Gleason 8-10 cancers (29 in the dutasteride arm vs. 19 in the placebo arm, $P = .15$), there was an increased risk of Gleason 8-10 cancers during years 3 and 4 of the study (1 in placebo vs. 12 in dutasteride, $P = .003$), although no additional Gleason 8-10 cancers were seen 2 years off-study among 2751 men assessed (Grubb et al, 2013). No deaths from prostate cancer were reported during the study, and there were no significant differences between treatment arms among detected cancers in terms of percentage or number of positive cores or tumor volume, even among Gleason 7-10 cancers. The rate of HGPIN was also significantly lower among men receiving dutasteride (3.8% vs. 4.9%, $P = .04$). Dutasteride also demonstrated beneficial effects on BPH outcomes (acute urinary retention and BPH-related surgery) and was generally well tolerated (15% drug-related adverse events in placebo arm vs. 22% in dutasteride arm). Dutasteride also appeared to have beneficial effects on PSA as a marker of prostate cancer (Marberger et al, 2012).

Summary. The PCPT and REDUCE confirm the consistency of effect of 5ARIs at reducing the risk of prostate cancer, with a similar magnitude of risk reduction across all subgroups. The fact that the results of REDUCE were congruent with those of the PCPT with respect to the magnitude of risk reduction, benefits on BPH end points, and minimal toxicity suggests that 5ARIs represent an effective primary prevention strategy. In 2010, the Oncology Drug Advisory Committee of the FDA convened to assess the evidence in support of 5ARIs as chemoprevention agents for prostate cancer. As part of its review, all biopsy specimens from the PCPT and REDUCE that showed prostate cancer were subject to central pathology review and regraded using the modified Gleason scale. The FDA reassessment showed a significant increase in Gleason 8-10 cancers across both trials (RR 1.7, 95% CI 1.2 to 2.3), suggesting that, for every 150 to 200 men treated with a 5ARI, one additional man would be diagnosed with high-grade prostate cancer to avert three to four low-grade cancers (Theoret et al, 2011). The committee believed that the post hoc exploratory analyses of PCPT and REDUCE did not provide convincing evidence that the increased incidence of high-grade cancer observed in both trials can be dismissed. The

FDA concluded that 5ARIs did not have a favorable risk-benefit profile for the chemoprevention of prostate cancer. Despite multiple analyses suggesting that detection bias accounted, at least in part, for the observed increase in the rate of high-grade tumors with 5ARIs, concern regarding this risk has all but eliminated the use of 5ARIs for prostate cancer prevention in common urologic practice. Several cost utility analyses have, however, suggested that chemoprevention with a 5ARI may be cost-effective in populations at high risk (Svatek, 2008; Kattan et al, 2011; Svatek and Lotan, 2011).

Toremifene Citrate

Toremifene citrate is a modulator of the ER and is FDA approved for the treatment of breast cancer. In vitro studies in prostate cancer have shown that low-dose toremifene selectively inhibits ER- α , which serves as a mediator of growth-stimulatory signal transduction and has direct antiproliferative effect through ER- β . A randomized trial in 1467 men with HGPIN failed to show a reduction in prostate cancer incidence at 3 years among those receiving toremifene citrate 20 mg daily versus placebo, even among select high-risk groups (Taneja et al, 2013).

Other Pharmacologic Agents

Interest in metformin as a chemopreventive agent is based on epidemiologic evidence showing a link between obesity, metabolic syndrome, and high circulating insulin levels and the development of various cancers. However, studies to date have failed to show a relationship between use of metformin and prostate cancer risk (Margel et al, 2013). Epidemiologic studies have shown an inverse relationship between nonsteroidal anti-inflammatory drug (NSAID) use and the risk of many cancers, including prostate cancer. However, a nested case-control study failed to show a dose-response or duration-response relationship between five different classes of NSAIDs (including aspirin) and the risk of prostate cancer (Mahmud et al, 2011).

Statins are widely used cholesterol-lowering drugs and are hypothesized to play a role in the prevention of cancer by inhibition of inflammation, angiogenesis, alteration of steroid-hormone biosynthesis or metabolism, cell cycle regulation, or promotion of apoptosis in tumor cells (Murtola et al, 2008). Several observational studies have shown an inverse association between statin use and risk of prostate cancer (including one that showed a reduction in mortality from prostate cancer) (Graaf et al, 2004; Shannon et al, 2005; Platz et al, 2006; Bansal et al, 2012; Marcella et al, 2012; Geybels et al, 2013), although others found no association (Flick et al, 2007; Agalliu et al, 2008) and two studies showed an increase in overall prostate cancer risk (Kaye and Jick, 2004; Murtola et al, 2007). Randomized trials of statin use to prevent cardiovascular disease reported no associations with prostate cancer incidence, though such trials were limited by short durations of statin use, brief follow-up periods, and relatively young participants who develop few cancers (Baigent et al, 2005; Dale et al, 2006; Browning and Martin, 2007). A meta-analysis of six randomized clinical trials, six cohort studies, and seven case-control studies found no association between statin use and overall prostate cancer incidence, but did find a protective association with advanced prostate cancer (HR 0.77, 95% CI 0.64 to 0.93) (Bonovas et al, 2008). This finding suggests an effect of statins at a late stage in carcinogenesis (e.g., tumor progression).

Vitamins and Micronutrients

Selenium and Vitamin E

The Selenium and Vitamin E Cancer Prevention Trial (SELECT) was a randomized, placebo-controlled, population-based primary chemoprevention trial designed to test the efficacy of selenium and vitamin E alone and in combination in the prevention of prostate cancer (Lippman et al, 2005). The rationale for using selenium was based on a secondary analysis of the Nutritional

Prevention of Cancer Trial of oral selenized yeast for nonmelanoma skin cancer in which men randomized to selenium versus placebo had a 65% reduction in prostate cancer incidence over a mean follow-up of 4.5 years (Clark et al, 1996). The rationale for vitamin E was based on the Alpha-Tocopherol, Beta-Carotene (ATBC) Lung Cancer Prevention Study for lung cancer incidence and mortality in which male smokers were randomized to α -tocopherol (50 mg daily) and β -carotene (20 mg daily) alone or in combination versus placebo (The effect of vitamin E, 1994). On secondary analysis, the ATBC study found a statistically significant 32% reduction in prostate cancer incidence in those receiving α -tocopherol (Albanes et al, 1995).

SELECT randomized 35,533 men to four treatment arms (selenium + placebo, vitamin E + placebo, selenium + vitamin E, and placebo + placebo) (Lippman et al, 2009). Eligibility criteria included age 50 years or older for African-Americans, age 55 years or older for Caucasians, a DRE not suspicious for cancer, serum PSA 4 ng/mL or less, and normal blood pressure. The primary end point was biopsy-confirmed prostate cancer, though the indications for biopsy were not dictated by protocol. Although the study duration was planned for 12 years, the independent data and safety monitoring committee recommended discontinuation of the study after the second interim analysis at 7 years because the data convincingly demonstrated no effect on the risk of prostate cancer by either agent alone or in combination, and no chance of a beneficial effect of the hypothesized magnitude with continued supplementation (Lippman et al, 2009). HRs for prostate cancer were 1.13 (99% CI 0.95 to 1.13) for vitamin E, 1.04 (99% CI 0.87 to 1.24) for selenium, and 1.05 (99% CI 0.88 to 1.25) for selenium and vitamin E. A follow-up study that included an additional 54,464 person-years showed that dietary supplementation with vitamin E actually increased the risk of prostate cancer (HR 1.17, 95% CI 1.004 to 1.36, $P = .008$) (Klein et al, 2011) (Fig. 107-13). Secondary analyses also showed no effect on the risks of lung, colorectal, or overall cancer incidence, no effect on cardiovascular events, and no effect on overall survival.

The absence of a beneficial effect of these micronutrients on prostate cancer risk was also observed in other randomized trials (Gaziano et al, 2009; Algotar et al, 2013). Two randomized trials have evaluated the effect of selenium, vitamin E, and/or soy on the risk of prostate cancer among men with evidence of HGPIN on prior biopsy. Southwest Oncology Group trial 9917 randomized 423 men with HGPIN to selenium 200 μ g/day versus placebo and found no difference in the 3-year risk of prostate cancer (36% vs. 37%, $P = .7$), although men with lowest baseline plasma selenium levels experienced a non-statistically significant risk reduction (Marshall et al, 2011). A similar trial from the National Cancer Institute of Canada randomized 303 men with HGPIN to daily soy (40 g), vitamin E (800 units), and selenium (200 μ g) versus placebo and found no significant reduction in prostate cancer risk at 3 years (HR 1.03, 95% CI 0.7 to 1.6, $P = .9$) (Fleshner et al, 2011).

Together, these results suggest that neither selenium nor vitamin E should be used in the hope of preventing prostate or other cancers. The 17% increased prostate cancer risk associated with vitamin E in SELECT demonstrates the potential for seemingly innocuous yet biologically active substances to cause harm. The reasons why these trials failed to confirm the presumed cancer-preventive activity of micronutrients are uncertain. A possible explanation is that men in earlier trials were relatively deficient in these micronutrients compared to those enrolled in the more recent trials. Thus, micronutrients may have cancer-preventive activity in deficient individuals but have no benefit (and potentially harm) in those who are nutritionally replete.

Soy

Soy products are a concentrated source of isoflavones, including genistein, daidzein, and their metabolites, which inhibit benign and malignant prostatic epithelial cell growth, downregulate androgen-regulated genes, and reduce tumor growth in animal models. Migration studies and lower prostate cancer rates in Asian

Figure 107-13. A-C, Cumulative incidence of prostate cancer detection over time by intervention group in the Selenium and Vitamin E Cancer Prevention Trial (SELECT). Those taking vitamin E alone (A) had a 17% increased risk of prostate cancer compared to placebo (HR 1.17, 99% CI 1.004 to 1.36, $P = .008$); rates of prostate cancer in the selenium alone arm (B) and the selenium plus vitamin E arm (C) were not different than placebo (HR 1.09, 99% CI 0.93 to 1.27, $P = .18$ and HR 1.05, 99% CI 0.89 to 1.22, $P = .46$, respectively). (Modified from Klein EA, Thompson IM Jr, Tangen CM, et al. Vitamin E and the risk of prostate cancer: the Selenium and Vitamin E Cancer Prevention Trial (SELECT). JAMA 2011;306:1549–56.)

men, for whom soy is an important component of the diet, support its role as an anticancer agent. However, as mentioned, a randomized trial of daily selenium, vitamin E, and soy versus placebo failed to reduce the risk of prostate cancer in men with HGPIN (Fleshner et al, 2011).

Lycopene

Lycopene is a red-orange carotenoid found primarily in tomatoes and tomato-derived products and other red fruits and vegetables. Lycopene is a potent antioxidant and there is mixed epidemiologic evidence that lycopene consumption is associated with a lower risk of prostate cancer (Giovannucci, 1999). Two prospective nested case-control studies in PLCO trial and PCPT patients examined the association of lycopene (either by serum levels or reported intake of tomato-containing foods) and prostate cancer risk and found no protective effect (Peters et al, 2007; Kristal et al, 2011). A meta-analysis of three small randomized, placebo-controlled studies of 154 patients failed to show a protective effect of lycopene on prostate cancer risk (Ilic et al, 2011).

Green Tea Catechin

Interest in green tea as a chemopreventive agent is based on epidemiologic observations of a low incidence of prostate cancer among Asians with a high dietary intake. Green tea catechins (which account for 30% to 40% of extractable solids from dried green tea leaves) have been shown to induce apoptosis and inhibit prostate cancer cell growth in vitro. In a small randomized, placebo-controlled trial in 60 men with HGPIN, green tea catechin was associated with a lower risk of prostate cancer compared to placebo (1 vs. 9) (Brausi et al, 2008). Confirmatory trials are needed to better assess the role of green tea consumption in prostate cancer prevention.

KEY POINTS: CHEMOPREVENTION

- The goal of primary chemoprevention is to decrease the incidence of a given cancer, simultaneously reducing both treatment-related side effects and mortality.
- Effective chemoprevention requires the use of nontoxic agents that inhibit specific molecular steps in the carcinogenic pathway.
- Prostate cancer is an attractive and appropriate target for primary prevention because of its incidence, prevalence, treatment-related morbidity, and disease-related mortality.
- Target populations appropriate for primary prevention studies can be subdivided into those with low, intermediate, and high risk of developing prostate cancer. The molecular mechanisms that underlie disease progression are likely to be different for each target population, and the results from a particular trial may not be generalizable to other clinical scenarios.
- The PCPT demonstrated that finasteride reduces the period prevalence of prostate cancer by 25%. The apparent increase in high-grade disease in men taking finasteride may be due to true biologic effect or due to ascertainment bias induced by the effects of finasteride on PSA, DRE, and prostate volume. The use of finasteride as a chemopreventive agent does not affect long-term survival among those with and without prostate cancer.
- SELECT demonstrated that neither vitamin E nor selenium prevents prostate cancer, and that the use of vitamin E was associated with an increased risk of prostate cancer.

CONCLUSION

It is clear that the process of prostate carcinogenesis is complex. The interplay of constitutional, behavioral, and molecular and environmental factors, against the backdrop of various processes occurring during aging, interact to set into motion a series of events that ultimately are manifested through the diagnosis of prostate cancer. Complicating the understanding of this process are various confounds associated with the diagnosis of the disease in clinical trials, in the general population, and in epidemiologic studies. Additionally, the current inability to distinguish biologically significant from biologically insignificant disease complicates full understanding of the interaction of these factors.

Despite promising outcomes from clinical trials for chemoprevention of prostate cancer, the relatively low use of and lack of enthusiasm for 5ARIs by prostate cancer specialists and primary care practitioners despite endorsement by professional societies and the subsequent failure of these drugs to gain regulatory approval by government agencies highlight the challenges of developing new agents and approaches to chemoprevention. The FDA poses a substantial obstacle because of intense scrutiny over toxicity, as was seen with 5ARIs. As was seen with SELECT, the promise of micronutrients as chemopreventive agents has fallen well short of expectations, and they may potentially be harmful. Future directions will require genetic and molecular approaches for identifying at-risk patients and appropriate targets for chemoprevention.

Biomarker Development

Blood-Based Biomarkers

Urine-Based Biomarkers

Tissue-Based Biomarkers

Summary

The field of prostate cancer biomarkers is currently in an era of rapid expansion. Over the past decade, appreciation of the heterogeneity of outcomes among men with clinically localized disease has matured. The clinical question has changed from one of diagnosis of prostate cancer to distinguishing aggressive from indolent disease. This fundamental adjustment in perspective has fueled avid research and development of novel biomarkers for prostate cancer.

Among urologic malignancies, prostate cancer has benefited greatly from the discovery and application of tumor markers. From its discovery in 1979 through clinical application in the late 1980s and 1990s, prostate-specific antigen (PSA) has evolved into an invaluable tool for detecting, staging, and monitoring prostate cancer in men. The widespread use of PSA screening has generated greater awareness about prostate cancer. During the PSA era, cancers identified when confined to the prostate have improved cure rates after either radical prostatectomy or radiation therapy. In the 1980s and early 1990s, most prostate cancers commonly arose through findings on an abnormal digital rectal examination (DRE) and/or elevated PSA, whereas today most prostate cancer arises as clinically nonpalpable (stage T1c) disease with PSA levels between 2.5 ng/mL and 10 ng/mL. Widespread application of PSA screening and the long natural history of prostate cancer have resulted in a stage migration to nonpalpable, clinically localized (stage T1c) disease and a parallel reduction in mortality (McCormack et al, 1995; Lilja, 1997; Pound et al, 1997; Stephenson and Stanford, 1997; Rittenhouse et al, 1998; Polascik et al, 1999; Pound et al, 1999; Diamandis et al, 2000). However, as mentioned, the clinical trajectory of these PSA-detected T1c cancers is far from homogeneous. Although PSA screening has improved survival, outcomes are not the same for all disease detected with PSA. Because many of these cancers may not pose a threat to survival (Diamandis et al, 2000; Yousef and Diamandis, 2001; Gretzer et al, 2002), the most common cause of mortality for *all* men with prostate cancer is heart disease. Our intention is not to downplay the influence of prostate cancer on the mortality of the approximately 30,000 men who die of prostate cancer annually in the United States, but rather to highlight the urgent need for reliable tools that allow the patient and physician alike to identify harmful cancers readily.

Although PSA is widely accepted as a prostate cancer tumor marker, it is organ specific and not cancer specific. Despite routine application of PSA assays, the limited specificity of this marker is highly controversial. There is significant overlap in serum PSA levels among men with cancer and men with benign disease. Elevated serum PSA levels may reflect alterations within the prostate secondary to tissue architectural changes such as cancer, inflammation, or benign prostatic hyperplasia (BPH). At the present time, serum PSA levels of 2.6 ng/mL are used as a threshold

to recommend prostate biopsy. With an extended pattern template biopsy approach, 40% of men presenting with an elevated PSA (serum PSA 4 to 10 ng/mL) may be diagnosed with cancer with a false-negative rate of 20%. In some instances, the biopsy needle may fail to sample representative areas (i.e., sample bias), failing to detect present cancer. To this end, application of PSA derivatives such as PSA density, PSA velocity, age-adjusted values, and, more recently, molecular derivatives have attempted to improve the performance of PSA.

There are four main domains in which clinically localized prostate cancer biomarkers are needed: (1) screening, (2) elevated PSA with prior negative biopsy, (3) pretreatment in men with a new diagnosis, and (4) postprostatectomy. By identifying men at greatest risk of harboring harmful disease, improved biomarkers used in screening could markedly reduce the number of men subjected to prostate biopsy. The cohort of men who have an elevated PSA, or for whom there is reasonable concern for cancer based on some other variable, after an initial negative biopsy represents a particularly vexing group. Although some biomarkers currently exist that address this situation, additional improvements in this regard would be helpful clinically. After a diagnosis of prostate cancer has been made, choosing a therapy can be challenging. Knowledge regarding biologic behavior could drastically improve the decision-making process for a patient contemplating therapy with curative intent (e.g., radical prostatectomy or radiation) versus active surveillance. Postprostatectomy biomarkers hold promise for improving the ability to identify candidates for adjuvant therapies.

New understanding of the molecular biology of carcinogenesis and prostate cancer is beginning to yield a new age in prostate cancer research. Advances in molecular oncology and breakthroughs in laboratory techniques have exponentially expanded the repertoire of innovative tools for discovery of novel ways of predicting the future. In this chapter, we discuss the process and phases of biomarker development, paying particular attention to scientific rationale and clinical application of blood-based, urine-based, and tissue-based biomarkers.

Several molecular approaches have been undertaken in pursuit of finding the optimal prostate cancer biomarker. An overview of basic cellular processes starts first with a DNA sequence (gene) that is transcribed to messenger RNA (transcript) and then translated to a protein that can carry out specific cellular functions (e.g., catalyze biochemical reactions leading to the formation of products such as metabolites). A guiding principle of prostate cancer biomarker development is that prostate cancer cells *a priori* are different in some molecular way compared with their benign counterparts. Another important observation is that aggressive prostate cancer cells are similarly different compared with their more indolent counterparts. The identification and quantification of these molecular

differences in tissues and bodily fluids form the basis of prostate cancer biomarker discovery.

BIOMARKER DEVELOPMENT

Although many groups are now developing methods for early detection of prostate cancer, the Early Detection Research Network (EDRN) has developed a particularly robust infrastructure for biomarker development. The EDRN is a program funded by the National Cancer Institute set forth with the objective to identify, develop, and validate promising biomarkers and technologies for early detection of cancer (Schedlich et al, 1987; Clements, 1989; Srivastava et al, 2001; Srivastava, 2014). The EDRN is part of the portfolio supported by the Division of Cancer Prevention. As suggested by its name, it is a network of academic centers working in collaboration with industry, public health groups, informatics centers, and patient advocates. The structure of the network consists of five scientific components, as follows.

The Biomarker Development Laboratories are responsible for discovery of novel biomarkers and technologies. They identify biomarkers and participate in the early phases of validation. The Biomarker Reference Laboratories facilitate the development and validation of assays that measure these new biomarkers. Without such efforts, results of assays may be difficult to reproduce when deployed at a different site. The Biomarker Reference Laboratories also assist in developing a more robust and efficient clinical assay. The Clinical Epidemiological Validation Centers are large clinical practices with infrastructure to procure ample clinical samples and to lead clinical trials. They are responsible for procuring samples for the Biomarker Development Laboratories. The Data Management and Coordinating Center is the spine of the network in the sense that it provides all the logistical and statistical support for all phases of development. This EDRN component is responsible for creating a reliable, secure, and practical means by which data may be collected for network studies. The fifth and final component is the Informatics Center, which is responsible for developing software for information management. As the EDRN experience grew, experts in oncology, clinical trials, biostatistics, and informatics came together and refined what is considered best practice for the development of new biomarkers (Young et al, 1995; Lilja, 1997; Rittenhouse et al, 1998; Pepe et al, 2001). Conceptually, progression of a biomarker through each of the five phases of development indicates increasing strength of evidence in favor of its clinical application.

Phase 1 consists of biomarker discovery. Although biomarker discovery may occur at any laboratory, the Biomarker Development Laboratories are intended to be factories of discovery along the lines of genomics, proteomics, glycomics, and metabolomics, in addition to traditional pathway science. The objective of this phase is to identify potential biomarkers and prioritize each for validation. The typical outcome of phase 1 development is a novel biomarker with some measure of test sensitivity and specificity in a subset of cancer and control subjects. In this way, a preclinical assay is moved forward into phase 2.

Phase 2 has the objective of measuring more reliably the sensitivity and specificity of the new biomarker in its ability to differentiate case status from control. The Biomarker Reference Laboratories often participate to optimize the clinical assay and assess the reproducibility of the assay in preparation for a clinical trial. It would not be unusual to see comparisons of biomarkers measured in tissue samples compared with levels from less invasive approaches such as voided urine or serum. If feasible, investigators may begin to study factors that affect expression of these biomarkers and the relationship of these biomarkers to cancer stage, grade, and prognosis. The clinical samples deployed at this stage tend to be more representative of the target population, and as a result, biomarkers may fail at this phase if they were initially developed on an overly selected set of tissues. The increasing inclination of many biomarker discovery programs is to employ more diverse cancer samples even during phases 1 and 2.

In phase 3, investigators examine the ability of new biomarkers to detect preclinical disease and evaluate how much lead time is provided by the biomarker relative to clinical presentation. The criteria necessary for a “positive test” are defined in this phase. Robust studies examining the impact of covariates on biomarker expression and measurement take place. Given the growing number of biomarkers, it would be common to see algorithms developed during this phase to support the use of panels of biomarkers as opposed to a single biomarker. The tissue repositories used for this phase are typically retrospective cohort studies in which clinical samples have been procured prospectively over time with careful annotation of clinical end points and risk factors. These subjects usually are identified before cancer is diagnosed, sometimes years before diagnosis. Although prospectively collected data are unnecessary in phase 3, the availability of such data provides for better statistical evaluations.

Having completed phase 3, a new biomarker would possess a validated clinical assay and strong evidence of ability to differentiate case from control according to its clinical indication conducted on a fairly robust sample of subjects. An understanding of factors that may affect measurement and expression of the biomarker is known, and plans are made for a prospective validation trial, which is phase 4.

In phase 4, indications for applying a new biomarker are clearly defined according to the labeling. Subjects are enrolled at the Clinical Epidemiological Validation Centers. Non-EDRN sites commonly are enlisted to satisfy the necessary power and recruitment timeframe. Potential subjects are identified for eligibility, given written consent, and are enrolled with careful annotation of all demographic, disease, risk factors, and cancer end points. The goal of phase 4 is to quantify the performance characteristics of a biomarker in the target population of interest. This quantification is typically done by examination of sensitivity, specificity, positive predictive value, and negative predictive value. Secondly, this phase also examines characteristics of cancers that are diagnosed using the biomarker, considers implementation feasibility and costs, and considers potential impact on overall mortality.

In contrast to drug studies, in which randomized clinical trials are conducted as validation of treatment effect, biomarkers are rarely tested with such trials given the large sample sizes, long durations, and prohibitive costs (Lundwall and Lilja, 1987; Andriole et al, 2009; Schröder et al, 2009). However, a robust clinical validation design specifically for biomarker discovery (Prospective Randomized Open, Blinded Endpoint [PROBE] study design) was proposed by Pepe and colleagues (2008) (Kumar et al, 1997; Lövgren et al, 1997; Takayama et al, 1997). Use of the PROBE design is intended to overcome spectrum bias, where there is differential selection of cases and controls. In addition, this approach overcomes ascertainment bias, defined as inclination for patients with different levels of the biomarker to undergo different diagnostic tests, because all subjects will receive the same testing. Within the EDRN, a common strategy has been to develop prospective registries to be used for validation studies by blinding samples, which are stored at the National Cancer Institute in Frederick, Maryland. In this way, validation studies can be performed using large cohorts for a series of biomarkers as long as sample size is sufficient.

Ultimately, it is desired that new biomarkers reduce the burden of cancer, and this takes place in phase 5—cancer control studies. With deployment over time, biomarkers are expected to identify cancers efficiently earlier in the disease course leading to greater construct validity. Achievement of a successful outcome in phase 5 requires reduction in cancer mortality that can be attributed to the biomarker use without prohibitive costs or overdiagnosis. This goal has been achieved by few biomarkers to date.

Inherently, the work necessary to take a biomarker from phase 1 through phase 5 often costs in excess of millions of dollars. A common strategy applied by the EDRN is to partner with multiple institutions and industry to fund work along different phases with a common goal of moving biomarkers into clinical practice that are likely to improve the health of a population. The approach of the

EDRN is not the only means by which biomarkers may be developed, but the outline developed by the EDRN scientists provides a rigorous framework for doing so.

Assessment of Biomarker Performance

In the previous section, we discussed study designs as applied by the EDRN in the development and validation of biomarkers. In this section, we briefly discuss common ways by which biomarker performance may be assessed. Typically, this assessment is conducted using the clinical grade assay in the intended population along the indicated clinical indications. Perhaps the most common means for assessing validity is calculation of sensitivity, specificity, and accuracy. Sensitivity is defined as the proportion of individuals with the disease who have a positive biomarker test, whereas specificity is defined as the proportion of individuals without the disease who have a negative test. Accuracy is the sum of true positives and true negatives divided by the total population. Sensitivity and specificity are graphically summarized using the receiver operating characteristic curve. This approach plots sensitivity on the vertical axis and $1 - \text{specificity}$ on the horizontal axis. In doing so, the area under the curve (AUC) is a measure of the accuracy of the test. An AUC of 1 signifies an ideal test, whereas an AUC of 0.5 indicates a poorly performing biomarker test.

Despite widespread use, sensitivity and specificity are not intuitive to interpret; positive and negative predictive values are often used instead. These values are calculated based on sensitivity and specificity and the prevalence of the disease. The definition of positive predictive value is the probability that a positive test indicates the presence of the disease state of interest. Similarly, negative predictive value is the probability that the patient does not have the disease state of interest when the biomarker test is negative. In many ways, these measures are more relevant to clinical practice, and there is an increasing tendency to use these as the end point for biomarker validation trials.

In prostate cancer early detection, it is useful to think in terms of pretest and post-test probability. When new biomarkers are introduced, the natural question becomes, "How much does this add to what we already know in terms of risk prediction?" The likelihood ratio (LR) is useful in this regard because the test indicates how much a new biomarker raises or lowers the probability of disease before biopsy. A positive LR is calculated as the probability of a positive test in patients with cancer divided by the probability of that test result in disease-free individuals. Similarly, a negative LR is calculated as the probability of a negative test result among healthy men divided by the probability of the same result among men with prostate cancer. An LR greater than 1 indicates that the test result increases the likelihood that a patient has cancer, whereas an LR less than 1 decreases the probability of the condition. In the literature, LRs greater than 5 or less than 0.2 are regarded as meaningful shifts in pretest probability.

At the present time, prostate biomarkers are proliferating at a greater rate thanks to the many innovations in high-throughput methods (Takayama et al, 2001; Prensner et al, 2012). Understanding the status of biomarkers with regard to U.S. Food and Drug Administration (FDA) approval and other approvals is helpful (Ablin et al, 1970; Sensabaugh, 1978; Kuriyama et al, 1980; Seamonds et al, 1986; Stamey et al, 1987; Oesterling et al, 1988; Füzéry et al, 2013). FDA approval is considered to be the final end point in the development process because it indicates governmental approval for a specific indication and provides for biomarker validity and safety. Such processes are not undertaken lightly and often cost millions of dollars. Currently FDA-approved biomarkers include PSA, free-to-total PSA ratio (%fPSA), Prostate Health Index (PHI), and PCA3. Another common term applied to new biomarkers is *CLIA-certified test*. The Clinical Laboratories Improvement Act (CLIA) laboratory standards established by the Centers for Medicare and Medicaid Services exist to ensure quality laboratory testing, but not necessarily biomarker validity or safety. The CLIA program examines performance characteristics of the tests with regard to laboratory precision, analytical sensitivity and specificity, reporting

Figure 108-1. Human kallikrein gene map. Map of the human kallikrein locus and corresponding proteins as described by Yousef and Diamandis (2001).

ranges, reference ranges, and criteria for the test systems. In contrast to FDA approval, a CLIA-certified test allows businesses to offer the test for commercial use, but it does not guarantee a biomarker has undergone rigorous clinical validation.

BLOOD-BASED BIOMARKERS

Prostate-Specific Antigen

Initially developed as a biomarker for monitoring patients with prostate cancer after treatment, PSA has become a lightning rod for controversy in the setting of prostate cancer screening. Given its unique prominence, a clear understanding of PSA is needed to lay the foundation for other potential prostate cancer biomarkers. Also known as human kallikrein peptidase 3 (hK3), PSA is a member of the kallikrein gene family (Fig. 108-1). Originally, only three genes of this family of genes were identified: the pancreatic/renal kallikrein (*hKLK1*), human kallikrein 2 (*hKLK2*), and PSA (*hKLK3*) genes (Yu et al, 1994a, 1994b, 1994c; McCormack et al, 1995; Lilja, 1997; Rittenhouse et al, 1998; Diamandis et al, 2000). With the subsequent identification of 12 other kallikrein genes, this family of proteases now consists of 15 members and is described with a distinct nomenclature (Monne et al, 1994; Diamandis et al, 2000; Yousef and Diamandis, 2001). These proteins all are serine proteases and are located on the long arm of chromosome 19 within the region spanning q13.2-q13.4. These serine proteases have similar amino acid sequences, with human kallikrein peptidase 1 (hK1) expressing 60% and human kallikrein peptidase 2 (hK2) expressing 78% homology with PSA (Schedlich et al, 1987; Clements, 1989; Yu and Diamandis, 1995). Both hK2 and hK3 (PSA) are released in zymogen form from the prostatic epithelium and are found in seminal fluid and serum. Because they share structural homology, both can form complexes with endogenous protease inhibitors such as α_2 -macroglobulin (A2M) and α_1 -antichymotrypsin (ACT) (Levesque et al, 1995; Young et al, 1995; Lilja, 1997; Rittenhouse et al, 1998).

To understand PSA and its related derivative biomarkers, it is important to understand how PSA is processed. PSA begins as a zymogen, termed *preproPSA*, which contains a 17–amino acid leader sequence (Lundwall and Lilja, 1987; Oesterling et al, 1988; Partin et al, 1990). Cleavage of *preproPSA* results in an inactive 244–amino acid proenzyme termed *proPSA*. Finally, cleavage of a leader amino acid sequence of *proPSA* by hK2 produces the active form of PSA (Kumar et al, 1997; Lövgren et al, 1997; Takayama et al, 1997; Magklara et al, 2000; Meng et al, 2002). Other prostate kallikreins, such as hK4, also may have a role in cleavage of *proPSA* (Lilja and Weiber, 1984; Lilja, 1985; McGee and Herr, 1988; Takayama et al, 2001).

PSA was first identified and purified in the late 1970s, but widespread use in clinical urology did not occur for another decade (Ablin et al, 1970; Sensabaugh, 1978; Kuriyama et al, 1980; Seamonds et al, 1986; Stamey et al, 1987; Oesterling et al, 1988; Christensson et al, 1990; McCormack et al, 1995; Otto et al, 1998). Although ectopic expression of PSA has been reported in smaller concentrations in the tissue of malignant breast tumors (Yu et al, 1994a, 1994b, 1994c; Partin et al, 2003), normal breast tissue (Christensson et al, 1990; Monne et al, 1994; Zhang et al, 2000), breast milk (Lilja et al, 1991; Yu and Diamandis, 1995; Végvári et al, 2010), and adrenal and renal carcinomas (Sensabaugh, 1978; Levesque et al, 1995; McCormack et al, 1995), PSA is highly organ specific because it is primarily produced by prostatic luminal

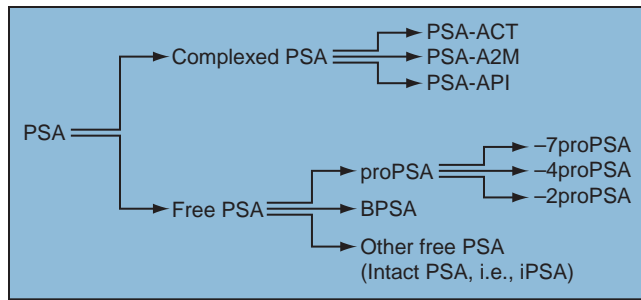

Figure 108-2. Molecular forms of prostate-specific antigen (PSA). Molecular derivatives of PSA include free PSA, such as proPSA (and the various clipped forms), benign prostatic hyperplasia-associated PSA (BPSA), and other free PSA forms such as intact, inactivated PSA. Complexed PSA includes free PSA that is bound to proteases such as α_1 -antichymotrypsin (ACT), α_1 -protease inhibitor (API), and α_2 -macroglobulin (A2M).

epithelial cells. As evidenced by its imperfect performance as a diagnostic biomarker, PSA is not cancer specific—there is substantial overlap in PSA values between men with benign versus malignant prostate disease (Oesterling et al, 1988; Partin et al, 1990; Catalona et al, 1991). On a per-gram basis, PSA is expressed to a greater degree in noncancerous relative to cancerous prostate tissue (Henttu et al, 1992; Magklara et al, 2000; Meng et al, 2002).

The function of this androgen-regulated protease is to liquefy semen through its action on the gel-forming proteins semenogelin and fibronectin within the semen after ejaculation (Lilja and Weiber, 1984; Lilja, 1985; Goldfarb et al, 1986; McGee and Herr, 1988). PSA is normally found in low concentration in serum (ng/mL). Within serum, PSA circulates in bound (complexed PSA) and unbound (free PSA [fPSA]) forms (Fig. 108-2). Three proteins that are known to bind to PSA in the blood are ACT, A2M, and α_1 -protease inhibitor (API) (Christensson et al, 1990; Vieira et al, 1994; McCormack et al, 1995; Otto et al, 1998). Binding of fPSA to ACT inactivates the protease, but the complex PSA-ACT remains immunodetectable (Meng et al, 2002; Partin et al, 2003).

Approximately 70% to 80% of PSA in serum is protein-bound, most to ACT in an irreversible fashion. Only 5% to 10% of PSA is bound to A2M, and 1% to 2% is bound to API. Binding of PSA to A2M still allows some proteolytic activity but renders the PSA-A2M complex undetectable by most current assays because all PSA epitope sites become masked (Fig. 108-3) (Christensson et al, 1990; Carter et al, 1992; Oesterling et al, 1993b; Zhang et al, 2000). PSA-ACT and PSA-API are detected by PSA assays, as is fPSA. fPSA without proteolytic activity is probably rendered inactive within the prostatic epithelial cell before release into the sera. This free inactive PSA does not form complexes with antiproteases, circulates unbound in sera, and is immunodetectable by current assays (Lilja et al, 1991; Oesterling et al, 1993a; Végvári et al, 2010). The primary release of PSA into the seminal fluid results in 10^6 -fold higher seminal concentrations than levels measured within serum (Sensabaugh, 1978; McCormack et al, 1995; Morgan et al, 1996; Fowler et al, 1999; Fowke et al, 2006). The concentrations found in seminal plasma range from 0.5 to 5.0 mg/mL, whereas the normal serum concentration in men 50 to 80 years old without prostate disease ranges between 1.0 and 4.0 ng/mL (Catalona et al, 1991; Fowke et al, 2006; Skolarus et al, 2007; Beebe-Dimmer et al, 2008).

PSA expression is strongly androgen dependent (Henttu et al, 1992; Ohwaki et al, 2010). Immunohistochemical detection of PSA within the prostate is characterized by bimodal peaks between 0 and 6 months of age and after 10 years of age, correlating directly with testosterone levels (Goldfarb et al, 1986; Stamey et al, 1987). Serum PSA becomes detectable at puberty with increases in luteinizing hormone and testosterone (Stamey et al, 1987; Vieira et al, 1994). In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume. On a per-cell basis, PSA expression is similar between benign and malignant prostate

Figure 108-3. Prostate-specific antigen (PSA)-binding proteases. A, Free PSA with A to E representing immunoreactive epitopes of free PSA. B, α_1 -Antichymotrypsin (ACT) blocks the E epitope during binding. C, α_2 -Macroglobulin (A2M) blocks all immunoreactive sites on PSA, making this derivative difficult to measure in serum.

cells (Armitage et al, 1988; Dalton, 1989; Nadler et al, 1995; Meng et al, 2002).

In men without BPH, the rate of change in PSA is 0.04 ng/mL per year compared with 0.07 to 0.27 ng/mL per year in men with BPH who are 60 to 85 years old (Carter et al, 1992; Yuan et al, 1992; Oesterling et al, 1993b). Cross-sectional data suggest that PSA increases 4% per milliliter of prostate volume and that 30% and 5% of the variance in PSA can be accounted for by prostate volume and age, respectively (Oesterling et al, 1993a; Kirkali et al, 1995). Black men without prostate cancer have higher PSA values than white men (Simak et al, 1993; Morgan et al, 1996; Heidenreich et al, 1997; Fowler et al, 1999; Fowke et al, 2006). Fowler and colleagues (1999) demonstrated that, on a volume/volume basis, the benign prostatic tissue of black men contributes more PSA to serum than the benign prostatic tissue of white men, a difference that increases with age. Body mass index also appears to affect PSA levels: Increasing body mass index is independently associated with decreasing serum PSA (Tchetgen et al, 1996; Herschman et al, 1997; Fowke et al, 2006; Skolarus et al, 2007; Beebe-Dimmer et al, 2008). Data from Ohwaki and colleagues (2010) suggest that this association may be secondary to hemodilution, as indicated by a close correlation between changes in serial hematocrit and serial PSA levels (Rajaei et al, 2013).

Elevated serum PSA levels are probably a product of disruption of cellular architecture within the prostate gland (Stamey et al, 1987; Mejak et al, 2013). The loss of the barrier afforded by the basal layer and basement membranes within the normal gland is a likely site for the egress of PSA into the circulation. This barrier loss can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (prostate massage, prostate biopsy) (Wang et al, 1981; Ercole et al, 1987; Stamey et al, 1987; Morote Robles et al, 1988). Prostatic inflammation (acute and chronic) and urinary retention can cause PSA elevations to variable degrees (Armitage et al, 1988; Dalton, 1989; Nadler et al, 1995; Thompson et al, 2003; Etzioni et al, 2005; Marks et al, 2006). Prostatic trauma, such as occurs after prostate biopsy, can result in a temporary spike in serum PSA that persists for 4 or more weeks before returning to baseline values (Yuan et al, 1992; Thompson et al, 2006; Kaplan et al, 2012).

Studies of the effect of ejaculation on serum PSA have shown no significant change in PSA (Kirkali et al, 1995; McCormack et al, 1995; Woodrum et al, 1998) and a significant decrease in serum PSA (Christensson et al, 1993; Leinonen et al, 1993; Lilja, 1993; Simak et al, 1993; Stenman et al, 1994; Catalona et al, 1997a; Heidenreich et al, 1997) in men 30 to 40 years old or younger. In men 50 years old and older, ejaculation can lead to a transient increase in PSA that may rarely result in a false-positive elevation (Tchetgen et al, 1996; Herschman et al, 1997; Catalona et al, 1998; Partin et al, 1998). However, PSA appears to return to baseline within 24 hours (Rajaei et al, 2013). Men presenting with a new

PSA elevation should be asked whether they engaged in sexual activity within 24 hours of PSA testing, and if the answer is yes, they should be asked to abstain before a repeat blood draw. Long-distance cycling is another potential cause of false PSA elevation, with PSA levels increasing by approximately 10% after bicycle rides exceeding 55 km (Mejak et al, 2013).

Although the above-mentioned factors can cause small-scale changes in PSA levels, the presence of prostate disease (prostate cancer, BPH, and prostatitis) is the most important factor affecting serum PSA (Wang et al, 1981; Ercole et al, 1987; Morote Robles et al, 1988). It is primarily the impact of BPH and prostatitis on PSA levels that confounds the accuracy of PSA in the screening setting. Prostate-directed treatment (for BPH and prostate cancer) can reduce serum PSA by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell. The 5 α -reductase inhibitors (5ARI), such as finasteride and dutasteride, have been shown to lower PSA levels by roughly 50% after 12 months of treatment (Guess et al, 1993); this has resulted in the so-called doubling rule, whereby PSA levels are multiplied by a factor of 2 in men undergoing 5ARI therapy to guide decisions regarding prostate cancer risk. However, using a multiple of 2 may overestimate PSA values in the first 6 months of treatment and underestimate PSA levels after several years of treatment (Thompson et al, 2003; Etzioni et al, 2005; Marks et al, 2006). Additionally, compelling data from the Prostate Cancer Prevention Trial and other sources suggest that 5ARI therapy substantially improves the performance characteristics of PSA in the screening setting with an AUC of 0.76 (finasteride) versus 0.68 (placebo) (Thompson et al, 2006; Kaplan et al, 2012). Interpretation of PSA values always should take into account the presence of prostate disease, previous diagnostic procedures, and prostate-directed treatments.

Free Prostate-Specific Antigen

Although most serum PSA is found complexed to proteases (primarily ACT), 5% to 45% of PSA exists as enzymatically inactive fPSA (Table 108-1) (McCormack et al, 1995; Woodrum et al, 1998). PSA produced from malignant cells appears to escape proteolytic processing more frequently, resulting in a greater fraction of serum PSA complexed to ACT and a lower percentage of total PSA (tPSA) that is free compared with men without prostate cancer (Christensson et al, 1993; Leinonen et al, 1993; Lilja, 1993; Stenman et al, 1994; Catalona et al, 1997a). This principle led to the development of fPSA testing as a means to improve the accuracy of PSA as a prostate cancer screening biomarker, and the FDA has approved its use in men with a serum total PSA level of 4 to 10 ng/mL and a negative DRE (Catalona et al, 1998; Partin et al, 1998). The %fPSA is most useful in the setting of PSA levels less than 10 ng/mL because the positive predictive value of tPSA greater than 10 to 20 ng/mL has been shown to be approximately 80%.

Numerous studies evaluated %fPSA cut points to determine potential thresholds that optimize the performance of this tool. Christensson and coworkers (1993) measured fPSA and tPSA fractions in men with and without prostate cancer and found that a fPSA/tPSA cutoff of 0.18 (18% fPSA) significantly improved the

ability to distinguish between subjects with and without cancer compared with use of tPSA alone. When using %fPSA cutoff values ranging from 14% to 28%, 20% to 65% of unnecessary biopsies may be avoided, while maintaining sensitivity rates of 70% to 95% within the tPSA range of 4 to 10 ng/mL (Pound et al, 1997; Stephenson and Stanford, 1997; Catalona et al, 1998; Partin et al, 1998; Polascik et al, 1999; Pound et al, 1999; Veltri and Miller, 1999; Vessella et al, 2000). In a prospective, multi-institutional study of men 50 to 75 years old with PSA levels between 4 and 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% detected 95% of cancers (sensitivity), while avoiding 20% of unnecessary biopsies (specificity) (Catalona et al, 1998; Gretzer et al, 2002). This resulted in an AUC for %fPSA that was significantly higher than that of tPSA (0.72 vs. 0.53). However, more recent data including men with 12-core prostate biopsy schemata showed a modest decrease in the AUC of %fPSA for cancer detection (Srivastava et al, 2001; Canto et al, 2004a; Srivastava, 2014). Although no single %fPSA threshold has been established, proposed cut points generally range from 15% to 25%. However, an important more recent development has been the increasing availability and usage of predictive tools that incorporate multiple clinical variables, such as tPSA, %fPSA, and DRE findings (Pepe et al, 2001; Hernandez et al, 2009; Zaytoun et al, 2011). In particular, the updated calculator based on results of the Prostate Cancer Prevention Trial (PCPT) provides a calibrated estimate of prostate cancer risk to facilitate shared clinical decision making (Fig. 108-4) (Andriole et al, 2009; Schröder et al, 2009; Ankerst et al, 2012).

Several studies have also evaluated the performance of %fPSA at tPSA levels less than 4.0 ng/mL because high-grade cancers do still occur at these low PSA levels (Thompson et al, 2004; Pepe et al, 2008). Catalona and colleagues (1997b) demonstrated that for men with PSA levels less than 4 ng/mL, a %fPSA cutoff value of 27% could detect 90% of cancers, while preventing 18% of unnecessary biopsies (Prensner et al, 2012). Comparison against PSA derivatives, such as prostate-specific antigen density, PSA velocity, and transition zone density, favored %fPSA in a similar cohort (Djavan et al, 1999; Füzyer et al, 2013). Haese and coworkers (1997) demonstrated that %fPSA in the tPSA range of 2 to 4.0 ng/mL does not substantially increase the number of biopsies needed to detect clinically significant prostate cancer compared with %fPSA in the 4 to 10 ng/mL range. In this study, a %fPSA cutoff value of 18% to 20% detected almost half of cancers and spared 73% of men from undergoing biopsy, with a biopsy-to-cancer ratio of 3:1 to 4:1.

In addition to contributing to detection, %fPSA may provide prognostic information. Serial measurement of %fPSA within archival serum demonstrated sustained differences between aggressive and nonaggressive prostate cancers (Carter et al, 1997). This study suggested that the longitudinal measurement of %fPSA changes not only may aid in detection but also may contribute information regarding disease behavior. Numerous studies reported on the correlation between %fPSA and pathologic outcomes, showing some correlation between low %fPSA and aggressive pathologic features (Morote et al, 2000; Aus et al, 2003; Shariat et al, 2006; Masieri et al, 2012). Additionally, Shariat and colleagues (2006) reported an independent association between lower %fPSA and biochemical recurrence in 402 men who underwent radical prostatectomy for clinically localized disease. These data stand in contrast to a study of 698 consecutive patients undergoing prostatectomy that found %fPSA did not independently predict aggressive pathologic features or biochemical recurrence (Graefen et al, 2002). Debate remains surrounding the utility of %fPSA as a prognostic biomarker.

There are some important caveats surrounding the interpretation of %fPSA in clinical practice for cancer detection. Factors such as prostatic manipulation, specimen handling, and assay variation have been shown to affect the interpretation of the ratio of fPSA to tPSA (Partin et al, 1996a, 1996b; Roth et al, 1998; Foj et al, 2014). Although there may be marginal changes in tPSA, fPSA levels may fluctuate, affecting the %fPSA calculation. Furthermore, because fPSA is cleared more rapidly from serum than complexed PSA

TABLE 108-1 Molecular Derivatives of Prostate-Specific Antigen

PSA TYPE	% IN SERUM
Complexed PSA	60-95
PSA-ACT	60-90
PSA-API	1-5
PSA-A2M	10-20
Free PSA	5-40

ACT, α_1 -antichymotrypsin; API, α_1 -protease inhibitor; A2M, α_2 -macroglobulin; PSA, prostate-specific antigen.

Results

Based on the provided risk factors a prostate biopsy performed would have a:

4% chance of high-grade prostate cancer,

10% chance of low-grade cancer,

86% chance that the biopsy is negative for cancer.

About 2 to 4% of men undergoing biopsy will have an infection that may require hospitalization.

Please consult your physician concerning these results.

Figure 108-4. Web-based calculation of prostate cancer risk using the PCPT risk calculator operationalized by the University of Texas Health Science Center at San Antonio (<http://deb.uthscsa.edu/URORiskCalc/Pages/calcs.jsp>). Distinct nomograms using different patient factors and biomarkers are available, and the output for the most commonly used nomograms gives the risk of high-risk cancer and any prostate cancer using a pictorial interface.

forms, the resulting calculated %fPSA is directly affected. It is recommended that PSA determinations be avoided for several weeks after prostatic manipulation (i.e., surgery, biopsy, cystoscopy) (Partin et al, 1996b; Lein et al, 1997; Björk et al, 1998). Lastly, fPSA decreases in a similar fashion as tPSA in the setting of 5ARI therapy, and the percentage of fPSA is not altered significantly by these medications (Keetch et al, 1997; Pannek et al, 1998).

The clinical setting in which %fPSA is most often used is in patients with an elevated PSA and a prior negative prostate biopsy result (Stephan et al, 1997; Hayek et al, 1999; Djavan et al, 2000). Stephan and colleagues (1997) reported a 5% cancer underdiagnosis rate when using a %fPSA value of 21% to trigger repeat biopsy, and Catalona and colleagues (1997a) reported that a threshold of 30% detected 95% of cancers and avoided 12% of repeat biopsies. More recent European data reported an AUC of 0.73 for %fPSA in a repeat biopsy population, exceeding that of PSA and PCA3 (Auprich et al, 2012). At a threshold of 18%, %fPSA demonstrated a sensitivity of 85% and specificity of 41%. However, the AUC for %fPSA was only 0.52 in another European repeat biopsy cohort, suggesting a need for other biomarkers in this setting (Scattoni et al, 2013).

Free Prostate-Specific Antigen Isoforms

Free PSA in serum comprises three isoforms: proPSA, BPH-associated PSA (BPSA), and intact fPSA (Mikolajczyk et al, 2002; Jansen et al, 2009). These three isoforms exist in approximately

equal concentrations in serum, and each has shown promise as a prostate cancer biomarker. As discussed earlier, PSA originates with a 17-amino acid chain that is cleaved to yield a precursor inactive form of PSA termed proPSA (Zhang et al, 1995; Kumar et al, 1997; Mikolajczyk et al, 1997, 2000, 2001; Peter et al, 2001). As depicted in Figure 108-5, the precursor form of PSA contains a 7-amino acid proleader peptide, in addition to the 237 constituent amino acids of mature PSA, and is termed proPSA or [-7]proPSA. This leader amino acid chain is cleaved by hK2, resulting in the active form of PSA. Incomplete removal of the 7-amino acid leader chain results in various other truncated or clipped forms of proPSA. These include proPSAs with 2, 4, and 5 leader amino acids ([-2]proPSA, [-4]proPSA, and [-5]proPSA), and all are primarily expressed in the peripheral zone of the prostate. With cellular disruption, these enzymatically inactive forms circulate as free PSA and may constitute most of the circulating fPSA in patients with prostate cancer (Fig. 108-6) (Mikolajczyk et al, 1997).

Reports by Mikolajczyk and colleagues (2000, 2001) revealed significantly elevated levels of these truncated forms of proPSA in prostate cancer tissue. In particular, the [-2]proPSA isoform, cleaved between leucine 5 and serine 6 of the propeptide, has shown increasing promise as a serum prostate cancer biomarker (Le et al, 2010; Lazzeri et al, 2012, 2013). Although the underlying biology behind the increased levels of [-2]proPSA in prostate cancer remains unclear, it may be that the decreased PSA processing in prostate cancer results in a relative increase in proPSA and its cleaved forms, in particular, [-2]proPSA. Additionally, Makarov and coworkers

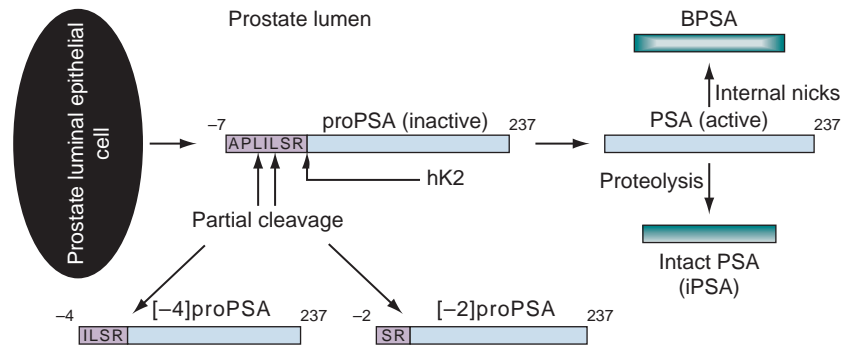

Figure 108-5. Differential cleavage and activation of pro-prostate-specific antigen (PSA). ProPSA is released from the prostate epithelial cell with a 7-amino acid leader sequence. hK2 cleaves the amino acid leader to activate PSA. Active PSA undergoes proteolysis to yield intact PSA (iPSA) and may undergo internal degradation to form benign PSA (BPSA). Partial cleavage of the 7-amino acid leader sequence yields inactive forms of proPSA (i.e., [-2]pPSA or [-4] pPSA).

Figure 108-6. Prostate-specific antigen (PSA) synthesis in normal versus cancer tissue. ProPSA is secreted into the lumen, where the 7-amino acid leader sequence is cleaved by hK2 to yield active PSA. Some of the active PSA diffuses into the serum, where it is bound to proteases such as α_1 -antichymotrypsin (ACT). The luminal active PSA undergoes proteolysis, and the resulting inactive PSA also may enter the circulation to circulate in the unbound or free state. In prostate cancer, loss of the tissue architecture may permit a relative increase in bound PSA and proPSA in serum.

(2009) proposed that proPSA production may be driven by benign tissue adjacent to malignant prostatic epithelium.

From a clinical standpoint, there are numerous reports supporting the utility of [-2]proPSA in the screening setting, either before initial biopsy or before repeat biopsy (Le et al, 2010; Guazzoni et al, 2011; Lazzeri et al, 2012, 2013). Lazzeri and colleagues (2013) reported on a prospective European cohort of 646 patients with tPSA between 2 ng/mL and 10 ng/mL who were undergoing initial prostate biopsy. The %[-2]proPSA was a strong independent predictor of prostate cancer at biopsy in a model that included fPSA and tPSA, and the AUC for %[-2]proPSA was 0.67. The %[-2]proPSA was also a strong predictor of prostate cancer with Gleason score 7 or greater in this study. In the United States, a prospective National Cancer Institute EDNRN validation study demonstrated excellent performance characteristics for %[-2]proPSA (Sokoll et al, 2010). Including %[-2]proPSA in the base model consisting of fPSA and tPSA significantly improved the predictive accuracy, and %[-2]PSA

outperformed PSA and %fPSA in predicting the presence of prostate cancer at the time of biopsy in patients with a serum tPSA of 2 to 10 ng/mL. Additionally, %[-2]proPSA was closely correlated with increasing Gleason score. The levels of [-2]proPSA have been incorporated into a formula that also includes fPSA and tPSA and is termed the Prostate Health Index (PHI) (Lazzeri et al, 2013). The PHI is FDA approved for men 50 years old and older with tPSA 4 to 10 ng/mL and negative DRE. This test is discussed in more detail in Chapter 111.

Another isoform of fPSA, BPSA, is identical to mature PSA except for internal cleavages between Lys182 and Lys145 (Mikolajczyk et al, 2002). Its expression is generally limited to transition zone tissue, and it is highly expressed in the setting of BPH (Mikolajczyk et al, 2000; Wang et al, 2000; Canto et al, 2004b). BPSA is closely related to prostate volume and does not appear to have any prognostic capacity in terms of distinguishing potentially indolent from aggressive disease (Naya et al, 2004; de Vries et al, 2005). Although serum BPSA alone is unlikely to differentiate between hyperplasia and cancer, in combination with assays for [-2]proPSA, it may allow additional discrimination (Stephan et al, 2009; Rhodes et al, 2012).

So-called intact PSA comprises an additional fPSA subset that has been identified as a potential predictive serum biomarker (Nurmikko et al, 2000; Steuber et al, 2007a; Hori et al, 2013). Preliminary studies demonstrated that the ratio of intact PSA to fPSA may improve the accuracy of prostate cancer detection (Nurmikko et al, 2000, 2001; Steuber et al, 2002). However, some studies of intact PSA include proPSA in their intact PSA assay, making it difficult to determine the predictive value of intact PSA alone (Peltola et al, 2011). This parameter has been used primarily as part of a multikallikrein panel, which is discussed later on in this chapter (Vickers et al, 2008).

Prostate-Specific Membrane Antigen

The glycoprotein prostate-specific membrane antigen (PSMA) has been evaluated for many years as a potential serum, urine, or tissue biomarker of prostate cancer. A folate hydrolase, PSMA is found embedded within the cell membrane of all prostatic epithelial cells. It is a type II transmembrane protein with an extracellular C-terminus that exists as a dimer and binds glutamate and glutamate-like structures (Fair et al, 1997; Israeli et al, 1997). The gene for PSMA has been cloned, fully sequenced, and localized to the short arm of chromosome 11 (11p11-p12). Although PSMA is predominantly expressed in the secretory acinar epithelium of the prostate gland, it has been isolated in other tissues, including in the central nervous system (astrocytes and Schwann cells) and intestine (jejunal brush border). In the brain, PSMA functions to metabolize the neurotransmitter *N*-acetylaspartylglutamate. In the intestine, PSMA

works as a carboxypeptidase and is known as glutamate carboxypeptidase type II.

Of interest for diagnosis (Douglas et al, 1997), prognosis (Perner et al, 2007), and imaging (Ristau et al, 2014) is the discovery of elevated expression of this protein in tissue from prostate cancer compared with normal prostate tissue (Silver et al, 1997; Chang et al, 1999; Elgamal et al, 2000; Minner et al, 2011). Multiple monoclonal antibodies have been designed to identify the intracellular and the extracellular domains of the PSMA protein; however, few have shown “diagnostic promise” immunohistochemically or as serum and/or urine assays (Horoszewicz et al, 1987; Douglas et al, 1997). However, PSMA mRNA expression among prostate cancers is highest in the hormone-deprived state (Henttu et al, 1992; Israeli et al, 1994). During cancer progression, differentially expressed variants of PSMA have been identified. Of three alternatively spliced variants of PSMA, one, known as PSM', is differentially expressed in normal tissue, BPH, and prostate cancer. Su and colleagues (1995) demonstrated that the PSMA/PSM' ratio is upregulated threefold to sixfold in prostate cancer compared with BPH (0.76 to 1.6) and normal (0.075 to 0.45) tissue. Xiao and colleagues (2001) reported use of an immunoselective (surface-enhanced laser desorption ionization) assay for PSMA and were able to differentiate cases of prostate cancer from BPH. There is also evidence that increased tissue expression of PSMA may confer a worse prognosis in patients undergoing radical prostatectomy (Perner et al, 2007; Minner et al, 2011). The development of an accurate enzyme-linked immunosorbent assay for PSMA in serum has potential significance for diagnostic and prognostic evaluation for prostate cancer. However, at the present time, PSMA appears to have its greatest use in targeted imaging and therapeutics, and promising ongoing trials exist in both of these settings (Milowsky et al, 2007; Barrett et al, 2013; Tagawa et al, 2013; Osborne et al, 2014).

Human Kallikrein 2

hK2 shares many important properties with PSA and has demonstrated potential as another prostate cancer tumor marker (Young et al, 1992; Darson et al, 1997; Kumar et al, 1997; Rittenhouse et al, 1998; Lövgren et al, 1999; Becker et al, 2000a). Among many similarities, hK2 and PSA share 80% amino acid homology (see Fig. 108-1), exhibit similar specificity for prostate tissue, and are hormonally regulated by androgens. As discussed earlier, one of the key functions of hK2 is to activate the zymogen proPSA to the active PSA through cleavage of the amino acid presequence (see Fig. 108-6).

The concentration of hK2 in prostatic tissue, seminal fluid, and serum is less than 2% that of tPSA (Young et al, 1992; Darson et al, 1997; Lövgren et al, 1999). As with PSA, hK2 in serum may be either protein bound or free, with most existing in the free state. Critical to its utility as a biomarker, hK2 expression varies independent of PSA expression in tissue and serum (Tremblay et al, 1997). For example, in benign epithelium, PSA is intensely expressed compared with minimal immunoreactivity of hK2 (Tremblay et al, 1997; Darson et al, 1999). In contrast, in cancerous tissue hK2 is expressed more intensely. Tissue expression of hK2 appears to correlate with more aggressive pathologic features, including Gleason grade (Darson et al, 1997; Tremblay et al, 1997; Darson et al, 1999).

As a serum biomarker, hK2 has been studied extensively and continues to hold promise. Numerous studies have shown an association between serum hK2 levels and the presence of prostate cancer, suggesting that it may be used in conjunction with PSA to improve the selection of patients for prostate needle biopsy (Becker et al, 2000b; Nam et al, 2000; Vickers et al, 2007). Furthermore, men with low-grade disease have lower concentrations of serum hK2 than men with more aggressive cancer (Darson et al, 1999). To improve the performance of hK2 as a biomarker, studies evaluated the ratio of hK2 to fPSA and/or tPSA. For men with tPSA in the range of 4 to 10 ng/mL, hK2/fPSA significantly differentiated prostate cancer from BPH, whereas hK2/tPSA did not (Becker et al,

2000b). Data from a multicenter study demonstrated a statistically significant difference among men with biopsy results positive for cancer, looking at hK2 alone and in combination with fPSA/tPSA (Kwiatkowski et al, 1998). Combining %fPSA and hK2/fPSA, Partin and associates (1999) demonstrated an increased cancer detection rate within the tPSA range of 2 to 10 ng/mL. Serum hK2 also may offer prognostic information, with studies showing correlations with aggressive pathologic features and biochemical recurrence (Haese et al, 2001; Steuber et al, 2007b).

Perhaps the most promising use of hK2 as a prostate cancer biomarker is through the development of the 4Kscore, a multi-kallikrein panel reported by Vickers and coworkers (2008). These authors used a large cohort of men from the Göteborg arm of the European Randomized study of Screening for Prostate Cancer (ERSPC) to combine, within a statistical model, four kallikrein forms (tPSA, fPSA, intact PSA, and hK2) to predict accurately the presence of prostate cancer in men with a PSA 3.0 ng/mL or greater (AUC 0.84). These findings were validated in a separate ERSPC cohort (Rotterdam arm) in which it was suggested that use of the multi-kallikrein panel could avoid 513 of 1000 biopsies with only 54 of 177 missed low-grade cancers and 12 of 100 missed high-grade cancers (Vickers et al, 2010). Additionally, of 392 men in this arm who underwent radical prostatectomy during the period 1994 to 2004, the four kallikrein markers were independently associated with pathologically aggressive disease features and improved the accuracy of the base model (AUC 0.81 to 0.84) (Carlsson et al, 2013). A commercial assay based on this panel is now available (Parekh et al, 2014; Bryant et al, 2015).

Additional Kallikrein Tumor Markers

In addition to PSA (hK3) and hK2, 13 other kallikrein genes have been identified (Paliouras et al, 2007). All kallikreins are expressed in normal prostate tissue, and the expression products of these genes have demonstrated potential as prostate cancer tumor markers (Shaw and Diamandis, 2007). Many of these proteases have a highly conserved structural organization and have been shown to contribute to biologic events such as angiogenesis and growth factor release (Diamandis and Yousef, 2001). Study of these proteins suggests interaction among the kallikreins in pathways that affect normal physiologic and pathologic processes (Yousef and Diamandis, 2002). Among these genes, studies have evaluated *KLK4*, *KLK14*, and *KLK15* in particular as promising prostate cancer biomarkers, albeit primarily in tissue rather than serum (Schmitt et al, 2013). *KLK4* mRNA was found to be expressed at higher levels in most prostate cancer tissues compared with matched normal prostate tissues (Obiezu et al, 2002; Xi et al, 2004; Klok et al, 2007) and may represent a therapeutic target (Jin et al, 2013). *KLK14* and *KLK15* may be markers of poor prognosis (Stephan et al, 2003; Yousef et al, 2003; Rabien et al, 2008). Rabien and colleagues (2008) demonstrated the association of *KLK14* levels on immunohistochemical staining with biochemical progression after radical prostatectomy among men with prostate cancer. Similarly, Mavridis and colleagues (2013) showed an independent correlation between *KLK15* expression and biochemical recurrence in 150 patients who underwent radical prostatectomy for prostate cancer.

Endoglin

Endoglin is a transmembrane glycoprotein that is otherwise known as CD105 and serves as a cell surface coreceptor for transforming growth factor β 1 and β 3. It has a key role in angiogenesis and tends to be located and expressed in vascular endothelial cells. Although initial studies demonstrated increased endoglin expression in prostate cancer tissue (Wikström et al, 2002), investigators examined the possibilities for detecting endoglin in the plasma and in the urine of men with prostate cancer. Preoperative plasma endoglin is associated with node-positive disease in patients undergoing radical prostatectomy and independently predicts biochemical recurrence (Karam et al, 2008; Svatek et al, 2008). Similarly, when endoglin is used in combination with several other blood-based

biomarkers, further discrimination regarding the risk for biochemical recurrence is provided (Svatek et al, 2009). Endoglin also is expressed in the urine of men with prostate cancer compared with men with negative biopsy results after each group received a DRE. These urinary levels correlate with tumor volume and appear to be more accurate than PSA in the discrimination of biopsy outcome (Fujita et al, 2009). Although these initial studies have been intriguing, further validation in multi-institutional trials is required to understand better the clinical utility of endoglin as a prognostic biomarker.

Circulating Tumor Cells

Circulating tumor cells (CTCs) have long been touted as potential prognostic biomarkers and treatment response indicators. The excitement in this area of research goes back more than 20 years when investigators demonstrated the ability to detect PSA mRNA in the blood of men with advanced prostate cancer (Katz et al, 1994). Subsequent CTC research in prostate cancer has used a wide range of methods, capitalizing on features such as size, surface marker expression, and cellular plasticity that differentiate CTCs from circulating mononuclear cells in the blood (Pantel and Alix-Panabières, 2010; Danila et al, 2011b; Yu et al, 2011). Typically, CTCs are defined as being CD45 negative and positive for an epithelial marker such as epithelial cell adhesion molecule (EpCAM) and/or cytokeratin. Critically, there is no single gold standard definition or methodology for isolating CTCs. As a result, the development of CTCs as a prostate cancer biomarker has been relatively slow to evolve, and comparing data among studies continues to be challenging.

At the present time, there is only one FDA-approved methodology for identifying CTCs: CellSearch (Veridex, Warren, NJ). The CellSearch system uses antibodies against EpCAM for CTC capture and stains with antibodies against CD45 (negative) and cytokeratins 8, 18, and 19 (positive) to identify individual CTCs. With this system, a CTC count of 5 or more cells per 7.5 mL of blood at any time during the course of the disease has been associated with a poor prognosis in prostate, breast, and colorectal cancers (Cristofanilli et al, 2004; Shaffer et al, 2007; Cohen et al, 2008; de Bono et al, 2008). In a study of 422 patients with metastatic prostate cancer, using the Veridex platform, the investigators demonstrated that there was a difference between baseline numbers of cells and cells present 2 to 5 weeks after treatment (Fig. 108-7). For example, 57% of the patients had more than 5 cells per 7.5 mL of blood before treatment, and 39% had more than 5 cells per 7.5 mL after treatment (Shaffer et al, 2007). Similar studies lent further support to the potential use of CTCs as a response indicator, with conversion from unfavorable to favorable CTC counts (<5 CTCs) frequently occurring in men with advanced prostate cancer receiving hormonal agents or chemotherapy (de Bono et al, 2008; Danila et al, 2010; Reid et al, 2010). Further data demonstrating that CTC response

independently predicts survival in these settings are needed before CTCs can be used as an efficacy-response surrogate marker (Scher et al, 2009, 2013).

Many other platforms for CTC detection have been developed, and this continues to be an area of rapid growth in the biomarker space. Investigators at Harvard Medical School developed a microfluidic system known as the “CTC-Chip,” which has garnered a great deal of attention (Nagrath et al, 2007). This system has a high level of sensitivity, able to detect a single EpCAM-positive cell among 1 billion blood cells, and the capture efficiency has been improved further with an updated device (Nagrath et al, 2007; Stott et al, 2010a). Additionally, it provides the opportunity subsequently to isolate and characterize these CTCs further (Stott et al, 2010b). Going forward, the use of CTCs as a biomarker will likely revolve less around simple enumeration and more around the specific molecular alterations that can be identified—either within the cells or from cell-free nucleic acids—providing a real-time “liquid biopsy” in men with prostate cancer (Danila et al, 2011a; Dawson et al, 2013; Danila et al, 2014).

Autoimmune Responses

Although we classically think of biomarkers as substances that are abnormally expressed by the tumors, the response of the body itself to the presence of the cancer cell can be a target for biomarker development. Using a high-throughput approach, investigators at the University of Michigan were able to develop autoimmune profiles that could distinguish individuals with prostate cancer from individuals without the disease with a great degree of accuracy (Wang et al, 2005). Similar results were observed elsewhere, confirming the potential for autoimmune signatures as potential diagnostic biomarkers (Massoner et al, 2012). Other studies have identified changes in leukocyte surface marker expression that may correspond with changes in the tumor microenvironment and could correspond with tumor aggressiveness (Hao et al, 2012; Zhong et al, 2012). There is a possibility that immune system markers may serve to reflect not only the presence of disease but also metastatic potential.

URINE-BASED BIOMARKERS

Prostate Cancer Antigen 3

Given the ease of collecting urine specimens and the known shedding of prostate cells into the urine, this body fluid has long held promise as a potential biomarker source in prostate cancer (Truong et al, 2013). However, urinary biomarkers of prostate cancer came into clinical use only more recently. The first of these, PCA3, initially was described by Bussemakers and colleagues (1999), who used differential display and Northern blot analysis to compare normal and prostate cancer tissue. They were able to identify a prostate cancer-specific gene on chromosome 9q21-22 that, although it does not encode a protein, is one of the most sensitive and specific prostate cancer biomarkers. Although its function remains unknown, multiple studies have demonstrated that PCA3 is a long noncoding RNA that is not expressed outside of the prostate, and PCA3 levels in malignant tissue generally far exceed levels in benign tissue (de Kok et al, 2002; Popa et al, 2007). Early studies used reverse transcriptase polymerase chain reaction assays to detect PCA3 in urine and showed improved performance characteristics for PCA3 over PSA in diagnosing prostate cancer (Hessels et al, 2003; van Gils et al, 2007).

More recently, a transcription-mediated amplification assay was developed, offering improved sensitivity and quantitation relative to standard reverse transcriptase polymerase chain reaction (Groskopf et al, 2006). This commercial assay (Progenesa; Hologic) is both CE marked and FDA approved (2012) to assist with decisions in the setting of a prior negative prostate needle biopsy result. To enhance the sensitivity of PCA3 detection, urine samples are collected after an “attentive” DRE involving three firm strokes on each lobe of the prostate toward the median sulcus (Fig. 108-8).

Figure 108-7. CellSearch Circulating Tumor Cell (CTC) cell enumeration system. The anti-EpCAM ferrofluid captures the cells, and they are validated with cytokeratin-positive and CD45-negative staining. EpCAM, epithelial cell adhesion molecule; CK, cytokeratin; CD45, CD stands for “cluster of differentiation,” which was originally known as leukocyte common antigen.

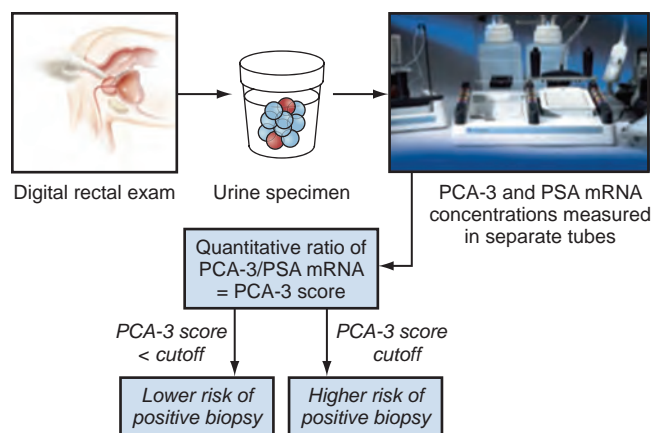

Figure 108-8. Prostate cancer antigen 3 (PCA3) assay protocol. Following an “attentive” digital rectal examination, urine is collected. Reverse transcriptase polymerase chain reaction determines the mRNA levels for PCA3 and prostate-specific antigen (PSA). The ratio of PCA3 to PSA determines the PCA3 score. The prostate cancer risk level suggests the need for biopsy. (From Groskopf J, Aubin SM, Deras IL, et al. APTIMA PCA3 molecular urine test: development of a method to aid in the diagnosis of prostate cancer. *Clin Chem* 2006;52:1089–95.)

The first 20 to 30 mL of voided urine should be collected within 1 hour (Sokoll et al, 2008). The commercial PCA3 score is reported as the ratio of urine PCA3 mRNA to urine PSA mRNA \times 1000, normalizing PCA3 expression to PSA expression.

Numerous clinical studies have been performed to evaluate the utility of urine PCA3 to serve as a prostate cancer biomarker, and all have shown that PCA3 scores are closely correlated with the likelihood of a positive biopsy (Hessels et al, 2003; Deras et al, 2008; van Gils et al, 2008; Roobol et al, 2010b). Deras and colleagues (2008) reported that men with a PCA3 less than 5 had a 14% positive biopsy rate compared with a 70% positive biopsy rate in men with PCA3 greater than 100. However, in another study, patients with PCA3 greater than 100 had only a 52% positive biopsy rate (Roobol et al, 2010a). In contrast to PSA, PCA3 levels are independent of prostate size (Haese et al, 2008).

A critical challenge in using PCA3—or any biomarker reported as a continuous score rather than just “positive/negative”—is establishing appropriate cutoffs. Given that PCA3 scores represent a continuum of risk, different thresholds lead to differences in sensitivity and specificity of the assay. Multiple cutoffs have been proposed, most commonly 10, 25, and 35 (Haese et al, 2008; Crawford et al, 2012). Haese and colleagues (2008) reported on a cutoff of 35, with positive biopsy results in 39% of cases above the threshold versus 22% of cases below the threshold. In a comparative effectiveness review commissioned by the U.S. Agency for Healthcare Quality and Research, Bradley and colleagues (2013) showed that a threshold of 25 results in a sensitivity of 74% and specificity of 57% (false-positive rate of 43%). The lower threshold of 25 was used in the FDA approval studies.

There are increasing reports on the use of PCA3 in the initial screening setting of patients without a prior biopsy. Roobol and colleagues (2010b) reported on a cohort of 721 men, most of whom had not previously undergone a biopsy, and showed that PCA3 (AUC 0.64) outperformed PSA (AUC 0.58) in predicting cancer on subsequent biopsy. In a prospective, community-based evaluation of PCA3 in 1962 men before any prostate biopsy, prostate cancer was detected in 61% of men with a PCA3 35 or greater and 32% with a PCA3 less than 35 (Crawford et al, 2012). The AUC for PCA3 was 0.71 compared with an AUC of 0.57 for PSA. Another study of 3073 men undergoing initial biopsy demonstrated that PCA3 was an independent predictor of any prostate cancer and high-grade prostate cancer after controlling for additional clinical variables (Chevli et al, 2014). Although PCA3 performed better than PSA for

the detection of any cancer (AUC 0.70 vs. 0.60), they performed similarly for the detection of high-grade cancer (AUC 0.68 vs. 0.68).

To improve the predictive accuracy of PCA3, numerous nomograms have been developed that incorporate PCA3 along with other known clinical predictors to identify men most likely to have a positive prostate biopsy. For example, Chun and associates (2009) showed that PCA3 improves the accuracy of a base clinical model (AUC 0.73 vs. 0.68) and proposed a final model incorporating a PCA3 cutoff of 17. Similarly, Ankerst and colleagues (2008) reported on an updated version of the PCPT nomogram that includes PCA3 as a continuous variable. The final model outperformed the base PCPT model (0.70 vs. 0.65) and has been operationalized on the Web (as in Fig. 108-4). Given the available data to date, the comparative effectiveness review by Bradley and colleagues (2013) concluded that PCA3 appears to be superior to tPSA in diagnosing prostate cancer, but that further evidence is needed, and there is no evidence at this point that use of PCA3 leads to better health outcomes.

Gene Fusions

With the landmark discovery of the presence of gene fusions in prostate cancer by Tomlins and colleagues (2005), considerable work has been done to determine their potential utility as prostate cancer biomarkers. In particular, fusions of the 5' untranslated region of the androgen-regulated gene transmembrane protease, serine 2 (TMPRSS2) with v-ets erythroblastosis virus E26 oncogene homolog (ERG) or ets variant 1 (ETV1) were found to be nearly 100% specific for prostate cancer and present in at least 50% of PSA-screened prostate cancers. Both ERG and ETV1 are members of the erythroblastosis virus E26 transformation-specific (ETS) transcription factor family, and TMPRSS2:ERG fusions represent about 90% of all ETS gene fusions (Tomlins et al, 2009; Young et al, 2012).

Although tissue-based detection of the fusion using either chromosomal analysis (i.e., fluorescence in situ hybridization) or immunohistochemical staining for ERG has shown some utility, this biomarker appears to have its greatest potential as a urine-based assay (Laxman et al, 2006; Hessels et al, 2007; Laxman et al, 2008). A feasibility study that examined urine samples after DRE confirmed that the TMPRSS2:ERG fusion can be detected in the urine and may aid in the decision to proceed with a prostate biopsy (Laxman et al, 2008). Similar to PCA3, TMPRSS2:ERG levels are normalized to urine PSA mRNA expression. Tomlins and colleagues (2011) reported on the development and use of a clinical grade assay based on transcription-mediated amplification (similar to the PCA3 assay) in 1312 men before prostate biopsy. TMPRSS2:ERG outperformed serum PSA for predicting the presence of prostate cancer with an AUC of 0.65 to 0.71 versus 0.59 to 0.61. Additionally, in a subset of men who underwent prostatectomy, a higher urine TMPRSS2:ERG score was associated with increased tumor volume, higher grade disease, and non-organ-confined cancer.

Moving toward the concept that single biomarkers will probably not answer the important clinical questions in prostate cancer alone, many investigators have begun to multiplex markers, resulting in additive value. Specifically, given that TMPRSS2:ERG is found in only half of all prostate cancer foci (approximately 75% of men with cancer), its greatest utility would be in combination with other biomarkers. It has been evaluated closely in concert with PCA3, and the two biomarkers together appear to provide improved performance over either one alone (Hessels et al, 2007; Laxman et al, 2008; Salami et al, 2013). In the cohort of 1312 patients reported by Tomlins and colleagues (2011), combining TMPRSS2:ERG and PCA3 scores with the PCPT nomogram resulted in an AUC for predicting cancer of 0.75 to 0.79. TMPRSS2:ERG + PCA3 score groups also were shown to correlate with features of disease aggressiveness such as Gleason grade, although data in this area continue to be mixed (Gopalan et al, 2009; Leyten et al, 2014).

Two other large studies reported on the combination of TMPRSS2:ERG and PCA3 for predicting the presence of prostate cancer. Cornu and coworkers (2013) showed that PCA3 and

TMPRSS2:ERG were each independent predictors of prostate cancer in a multivariable model that also included other clinical parameters. More recently, [Leyten and colleagues \(2014\)](#) reported on the prospective use of the combined assay in 497 patients at six centers in Europe. The combination of PCA3 and *TMPRSS2:ERG* increased the performance of the ERSPC risk calculator from an AUC of 0.80 to 0.84. Additionally, the sensitivity of PCA3 increased from 68% to 76% when *TMPRSS2:ERG* was added. The combined test is commercially available as the Mi-Prostate Score (University of Michigan Health System), combining serum PSA, urine PCA3, and urine *TMPRSS2:ERG* to provide a quantitative risk estimate of the likelihood of detecting prostate cancer on prostate biopsy as well as the probability of detecting high-grade cancer. This test also may have a role in the management of patients on active surveillance for prostate cancer because it has been correlated with features of tumor aggressiveness in a prospective active surveillance cohort ([Lin et al, 2013](#)).

Other Urine Biomarkers

Metabolomics

Cancer cells have long been known to harbor substantial metabolic modifications. However, even with the explosion of molecular biology and the large amount of information that has been learned about cell cycle regulation, little attention has been directed to the differences that exist between the metabolic processes of the cancer cell versus normal cells. More recently, high-throughput proteomics and metabolomics platforms combining chromatography with mass spectroscopy have revealed many potentially important differences in metabolomics profiles between benign and malignant prostate tissues. As a result, large tissue-based metabolomics signatures have been identified that can accurately identify prostate cancer and may provide prognostic information ([Jung et al, 2013](#); [Kami et al, 2013](#); [McDunn et al, 2013](#)). Studies of patients who underwent radical prostatectomy have reported several different metabolites that may predict biochemical recurrence independent of standard clinicopathologic features ([Jung et al, 2013](#); [McDunn et al, 2013](#)).

Based on the initial tissue-based work, urinary metabolomics profiles of prostate cancer have been identified that appear to have potential clinical applicability. Among the molecules profiled, perhaps the most prominent metabolite is sarcosine, a metabolite of glycine that has been demonstrated in the urine of men with prostate cancer ([Sreekumar et al, 2009](#)). [Sreekumar and colleagues \(2009\)](#) reported that not only could urinary sarcosine help distinguish malignant from benign prostate tissue, but also that sarcosine was associated with progression to metastasis. The Prostarix assay (Metabolon) is a commercial metabolomics panel derived from this research that uses post-DRE urine. This laboratory-developed test, which does not have FDA approval at the present time, seeks to aid in decisions surrounding the need to perform a prostate needle biopsy.

Annexin A3

Another potential urine-based prostate cancer biomarker is annexin A3, which is inversely related to the presence of prostate cancer. This protein is part of a family of calcium and phospholipid binding proteins that have been shown to be altered in cancer ([Wozny et al, 2007](#); [Köllermaier et al, 2008](#)). Evaluating annexin A3 concentrations in urine obtained after DRE before prostate needle biopsy, [Schostak and colleagues \(2009\)](#) evaluated the potential clinical utility of urine-based annexin A3, either as a stand-alone biomarker or together with PSA. In a blinded study that consisted of training and evaluation sets of 243 and 264 men, respectively, these investigators showed that annexin A3 added to the ability of PSA to predict a positive needle biopsy with a combined AUC of 0.81. Using a multiplex approach, [Cao and colleagues \(2011\)](#) reported on the combination of urine annexin A3, PCA3, *TMPRSS2:ERG*, and sarcosine to help identify patients with prostate cancer. The

multimarker model demonstrated a high level of predictive accuracy with an AUC of 0.84 in patients with PSA 4 to 10 ng/mL and an AUC of 0.86 across all patients in their cohort.

MicroRNA

Based on the realization that most of the DNA in the genome does not encode protein sequences, the utility of these sequences in the regulation of gene expression has been under intense investigation. Among the most important components of this type of regulation are microRNAs (miRNAs). These are small (approximately 19 to 22 nucleotides), noncoding single-stranded RNAs involved in the regulation of mRNA. They have been detected in a wide range of biologic fluids and are being explored as potential biomarkers in a variety of malignancies. Given their potential mechanistic role, they may provide diagnostic and prognostic information. In prostate cancer, miR-141 has shown promise in numerous studies in terms of its association not only with prostate cancer but also potentially with disease aggressiveness ([Mitchell et al, 2008](#); [Bryant et al, 2012](#)). Additionally, [Casanova-Salas and colleagues \(2014\)](#) reported that urine miR-187 is an independent predictor of prostate cancer at needle biopsy. Although these findings need to be expanded to larger populations, this remains a promising family of potential markers.

TISSUE-BASED BIOMARKERS

α -Methylacyl Coenzyme A Racemase

α -Methylacyl coenzyme A racemase (*AMACR*) gene, located on chromosome 5, is upregulated in prostate cancer tissues ([Luo et al, 2002](#); [Rubin et al, 2002](#)). *AMACR* functions as an enzyme responsible for the β -oxidation of branched-chain fatty acids obtained in diets consisting of beef and dairy products. [Luo and colleagues \(2002\)](#) demonstrated that 88% of prostate cancer cases and untreated metastases and hormone-refractory prostate cancers were strongly positive for *AMACR*. Immunohistochemical studies by [Rubin and coworkers \(2002\)](#) showed that *AMACR* expression in biopsy tissue may provide 97% sensitivity and 100% specificity for prostate cancer detection. In combination with other markers, such as TP63, that aid in identifying basal cells absent in prostate cancer, measurement of *AMACR* has the potential for the development of molecular probes to aid in the detection of prostate cancer. As a result, *AMACR* immunostaining is commonly performed on prostate needle biopsy specimens to confirm the presence of cancer. *AMACR* also may have some prognostic utility because decreased staining levels are associated with an increased risk of disease progression ([Rubin et al, 2005](#)). Although other roles for *AMACR* as a biomarker have shown some promise—for example, as a urinary assay for prostate cancer detection—the performance of serum and urine tests has not been sufficient to warrant clinical use to date.

Epigenetic Modifications

Changes in gene expression may occur as a result of alterations in DNA, and epigenetic changes are changes not caused by alterations in DNA sequence. These epigenetic modifications include changes in DNA methylation and histone acetylation status. Segments within the gene promoter that are composed of GC-rich regions are termed *CpG islands*. Alterations in the methylation status of these regions may affect gene expression and have been shown to play a role in carcinogenesis ([Jones and Baylin, 2002](#)). Furthermore, cumulative effects of environmental exposures, such as diet and stress throughout life, may affect DNA methylation status and contribute to the risk of cancer development ([Li et al, 2004](#)). The products of numerous hypermethylated genes have been implicated in development of prostate cancer, including glutathione-S-transferase π (*GSTP1*), adenomatous polyposis coli (*APC*), retinoic acid receptors beta 2 (*RARB2*), and RAS association domain family protein isoform A (*RASSF1A*) ([Mahapatra et al, 2012](#)).

GSTP1 belongs to a family of detoxifying enzymes that are involved in metabolic reduction of electrophilic carcinogens and was the first tissue methylation biomarker to be discovered. [Li and coworkers \(2004\)](#) noted that the *GSTP1* gene was unmethylated in all normal human tissues and BPH but was hypermethylated in all 20 prostate cancer specimens analyzed. [Harden and coworkers \(2003a, 2003b\)](#) used polymerase chain reaction to detect hypermethylated *GSTP1* in prostate biopsy specimens, and *GSTP1* methylation was detected in 11 of 15 (73% sensitivity) prostate cancer cases and in none of 14 (100% specificity) benign control cases. Quantitation of *GSTP1* hypermethylation accurately detected CaP even in small, limited tissue samples. Elevated levels of *GSTP1* CpG hypermethylation have been detected in tissues from precancerous lesions (atypia and prostatic intraepithelial neoplasia) and within ejaculates, urine, and plasma from men with prostate cancer ([Nakayama et al, 2003](#); [Bastian et al, 2005](#)). [Cairns and coworkers \(2001\)](#) demonstrated the presence of elevated *GSTP1* hypermethylation in 79% of prostate cancer specimens. *GSTP1* methylation appears to occur early in prostate carcinogenesis, and methylation levels may correlate with features of tumor aggressiveness ([Jerónimo et al, 2001](#); [Zhou et al, 2004](#)). In a more recent meta-analysis, *GSTP1* promoter hypermethylation was shown to have a sensitivity of 82% and specificity of 95% for distinguishing malignant from normal prostate tissue ([Van Neste et al, 2012](#)).

In addition to *GSTP1*, hypermethylation of other genes has been noted to occur in almost 100% of prostate cancers ([Mahapatra et al, 2012](#)). *APC* is a tumor suppressor gene involved in apoptosis and cell migration, and mutation of *APC* is often an early event in colon carcinogenesis. In a retrospective analysis assessing patients with newly diagnosed prostate cancer, *APC* methylation was associated with an independent 50% increase in the likelihood of death from prostate cancer ([Richiardi et al, 2009](#)). *RASSF1*, a gene involved in cell cycle regulation, and *RARβ2*, a nuclear transcriptional regulator, are other key genes methylated in a large proportion of prostate cancers and shown to distinguish benign from malignant prostate in a number of studies ([Zon et al, 2009](#); [Van Neste et al, 2012](#)).

Perhaps the most clinically relevant aspect of these methylation changes is the discovery that they are frequently detectable in normal tissue adjacent to tumors, but not in normal tissue well away from the primary tumor ([Richiardi et al, 2013](#)). These changes may be useful indicators of the field effect that has long been known to exist—the presence of molecular changes in histologically normal tissue bordering a tumor. In patients with a prior negative biopsy, the identification of these molecular changes in the original biopsy tissue may suggest an increased likelihood of occult prostate cancer. [Trock and colleagues \(2012\)](#) showed that methylation of *APC* in histologically negative prostate biopsy specimens predicted the presence of prostate cancer in 86 men undergoing repeat biopsy, with a negative predictive value of 0.96 and sensitivity of 0.95. Using a quantitative commercial methylation assay (ConfirmMDx; MDxHealth) that assesses methylation of *GSTP1*, *APC*, and *RASSF1*, [Stewart and associates \(2013\)](#) showed a negative predictive value of 0.90 and sensitivity of 0.68 for the presence of cancer. In this retrospective study, methylation status was an independent predictor of the presence of prostate cancer on repeat biopsy, suggesting accurate identification of at-risk patients based on the “halo effect” of aberrant methylation.

Genomic Expression Profiles

For more than a decade, a great deal of attention has been devoted to discovering large sets of genes that, when evaluated together as a single biomarker assay, perform far better than any individual gene on its own. Advances in genomics have facilitated the evaluation of gene expression in formalin-fixed paraffin-embedded tissue, which means that archived prostate specimens can be interrogated for expression of gene profiles that are associated with aggressive disease features. Gene expression profiling has been explored in numerous settings, resulting in genomic classifiers for response to chemotherapy in breast and colorectal cancers ([Iwao-Koizumi et al, 2005](#); [Del Rio et al, 2007](#)).

Numerous laboratory-developed tests using genomic expression profiling for risk stratification in men with prostate cancer are being developed and commercialized, including Prolaris (Myriad Genetics), OncotypeDx (Genomic Health), and Decipher (GenomeDx Biosciences). The Prolaris test assesses 31 cell cycle progression genes, and many studies have demonstrated an association between this gene signature and the risk of progression and death from prostate cancer ([Cuzick et al, 2011, 2012](#)). [Bishoff and colleagues \(2014\)](#) retrospectively assessed the performance of this assay on prostate needle biopsy specimens from men who underwent subsequent prostatectomy, demonstrating an independent association between cell cycle progression score and biochemical recurrence. This assay and OncotypeDx are primarily intended to help with management decisions in patients with newly diagnosed prostate cancer. The OncotypeDx classifier uses gene sets in several biologic pathways and has been developed to predict the likelihood of aggressive pathologic features at the time of prostatectomy ([Knezevic et al, 2013](#); [Klein et al, 2014](#)). Finally, the Decipher assay is a 22-marker genomic classifier that has been evaluated using tissue from prostatectomy specimens. In men with high-risk disease and men with biochemical recurrence, the genomic classifier was independently associated with the development of metastatic disease ([Karnes et al, 2013](#); [Ross et al, 2014](#); [Den et al, 2015](#)).

Gene Susceptibility Loci

Although 40% of prostate cancer risk may be related to hereditary factors, relatively little is known about the specific germline mutations that may contribute to prostate cancer risk ([Lichtenstein et al, 2000](#)). Identification of these mutations causing increased prostate cancer risk could have important implications for screening and early detection of patients at high risk of developing prostate cancer. That said, if an individual is found to have a fivefold increase in his risk for prostate cancer, what should be done? Should the individual be screened more carefully or more frequently? Should he simply undergo a prostate biopsy or treatment? These big questions are being actively investigated as part of the prospective IMPACT study, investigating methods of targeted screening in men with a genetic predisposition to prostate cancer ([Bancroft et al, 2014](#)).

Targeted screening requires the ability to identify at-risk patients, and many susceptibility loci involved in the risk of development of cancer have been reported ([Monroe et al, 1995](#); [Lichtenstein et al, 2000](#); [Nam et al, 2003](#); [Simard et al, 2003](#)). Genome-wide association studies have become one of the most common means of identifying key germline alterations that may predispose to the development of prostate cancer. These are case-control studies looking at common genetic variants, most commonly single nucleotide polymorphisms (SNPs), to identify specific ones associated with the development of prostate cancer. Although identified SNPs are generally not thought to drive the increased risk of prostate cancer, they serve as a surrogate of other nearby alterations that may cause functional changes driving eventual carcinogenesis ([Goldstein, 2009](#)). Genome-wide association studies have identified numerous potential variant alleles that are associated with the development of prostate cancer, with the 8q24 region most frequently arising as an SNP hot spot ([Al Olama et al, 2009](#)). The increased risk of prostate cancer associated with any individual SNP is relatively low but collectively may account for 25% of heritable prostate cancer risk ([Kote-Jarai et al, 2011](#)).

Also, several specific genes have been identified as mutated in a disproportionate number of patients with prostate cancer and appear to be frequently responsible for cases of hereditary prostate cancer, in particular, *BRCA1*, *BRCA2*, *HOXB13*, and the mismatch repair genes associated with Lynch syndrome (e.g., *MSH2*) ([Ewing et al, 2012](#); [Raymond et al, 2013](#); [Bancroft et al, 2014](#)). Recurrent mutations in these genes have been discovered in numerous familial prostate cancer cohorts. For example, [Ewing and colleagues \(2012\)](#) showed that the recurrent *HOXB13* G84E mutation significantly increased prostate cancer risk (relative risk 20.1, 95% confidence interval 3.5 to 803) and was present in 3% of men with early-onset familial prostate cancer compared with only 0.6% of

men with late-onset nonfamilial cancer. This finding emphasizes one of the critical aspects of these genetics studies: Familial prostate cancer often manifests at an earlier age and may be more aggressive on average than nonhereditary prostate cancer (Gallagher et al, 2010; Lange et al, 2012).

SUMMARY

Early detection when cancer remains confined to the prostate not only improves cure rates but also decreases mortality from prostate cancer. Although the discovery and application of PSA have revolutionized current prostate cancer detection and management, stage migration and changes in the natural history of this cancer have outrun the currently maximized application of this tumor marker. Application of various PSA derivatives, although improving

sensitivity, risks impairing specificity. The discovery of molecular derivatives of PSA, PCA3, new kallikrein markers, and gene rearrangements is leading to significant improvements in the efficiency of prostate cancer detection.

Innovations and new understanding in the field of molecular oncology have provided a host of potential prostate cancer tumor markers. Because prostate cancer has been shown to be a heterogeneous disease, it is likely that application of a panel of markers will ultimately provide added sensitivity and specificity for detection of the disease. Identification of hypermethylated regions, such as for *GSTP1*, as well as tissue-based genomic classifiers may improve the diagnostic and prognostic potential of prostate needle biopsies substantially. Development of these markers from research into clinically applicable tools will require clear demonstration of clinical utility, showing that these new assays have a real impact in the clinical care of men with prostate cancer.

KEY POINTS

- Today, most prostate cancer arises as clinically nonpalpable (stage T1c) disease with PSA between 2.5 and 10 ng/mL. The evolving demographics and natural history of prostate cancer have resulted in stage migration to nonpalpable, clinically localized (stage T1c) disease and a parallel reduction in mortality.
- Although PSA is widely accepted as a prostate cancer tumor marker, it is organ specific and not disease specific.
- In serum, PSA circulates in both bound and unbound forms. Three proteins that are known to bind to PSA in blood are ACT, A2M, and API.
- Although prostate cancer cells do not produce more PSA than benign prostate epithelium, the PSA produced from malignant cells appears to escape proteolytic processing. Thus, men with prostate cancer have a greater fraction of serum PSA complexed to ACT and a lower percentage of total PSA that is free compared with men without prostate cancer.
- Finasteride (5 mg) and other 5 α -reductase inhibitors used for treatment of BPH have been shown to lower PSA levels by an average of 50%.
- The role for %fPSA is more applicable to PSA levels less than 10 ng/mL because the positive predictive rate of total PSA greater than 10 to 20 ng/mL has been demonstrated to be as high as 80%.
- The EDRN has established a five-phase model of biomarker development, paralleling the phases of clinical trials for therapeutic agents.
- Although FDA approval is often desired, it is not necessary for commercialization of new biomarkers provided the test is CLIA-certified and run in a CLIA laboratory.
- There are four main domains in which clinically localized prostate cancer biomarkers are needed: (1) screening, (2) elevated PSA with prior negative biopsy, (3) pretreatment in men with a new diagnosis, and (4) postprostatectomy.
- PSA originates as a 17-amino acid chain (preproPSA) that is cleaved to yield an inactive precursor form termed proPSA. Cleavage of a leader amino acid sequence of proPSA by hK2 produces the active form of PSA.
- PHI is a multiplex diagnostic serum assay testing [-2]proPSA along with free and total PSA. It has been FDA-approved for men 50 years and older with total PSA 4-10 ng/mL and negative DRE.
- Immunohistochemical studies reveal different tissue expression patterns for hK2 and PSA. In benign epithelium, PSA is intensely expressed compared with the minimal immunoreactivity of hK2. In contrast, in cancerous tissue hK2 is expressed more intensely.
- The 4Kscore is derived from a serum assay testing total PSA, free PSA, intact PSA, and hK2. It is a diagnostic test intended for use in men with an elevated PSA considering prostate biopsy.
- PCA3 is a long noncoding RNA that is detectable in the urine and serves as a diagnostic prostate cancer marker. The commercially available ProgenSA assay evaluates PCA3 in post-DRE urine and is FDA approved for use in patients with an elevated PSA and prior negative biopsy.
- The *TMPRSS2:ERG* gene fusion is present in at least 50% of PSA-screened prostate cancers. While also a tissue biomarker, its most promising application currently appears to be as a urine biomarker as part of a multiplex assay with PCA3.
- Segments within the gene promoter that are composed of GC-rich regions are termed CpG islands. Alterations in the methylation status of these regions may affect gene expression and have been shown to play a role in carcinogenesis.
- Key hypermethylated genes that may have a role in prostate cancer include *GSTP1*, *APC*, *RAR β 2*, and *RASSF1A*. Hypermethylation changes are frequently detectable in normal tissue adjacent to tumors.
- Circulating tumor cells are being used as novel tools to correlate with response to therapy, as well as provide valuable resources with which to study metastatic disease.

Ultrasonographic Anatomy of the Prostate

Gray-Scale Transrectal Ultrasonography

Transrectal ultrasonography of the prostate (TRUS) has become a standard tool in the practice of urology. Many image-guided prostate cancer interventions, including initial prostate biopsy, follow-up biopsy for active surveillance, low- and high-dose brachytherapy, cryotherapy, and high-intensity focused ultrasound (US) rely on TRUS. Fiducial and radiofrequency markers are being placed under TRUS guidance for real-time tumor tracking of the prostate during radiation therapy (Linden et al, 2009; Das et al, 2014). Polyethylene glycol hydrogel injection into anterior perirectal fat to decrease rectal toxicity during prostate radiation therapy is another very new and evolving TRUS application (Strom et al, 2014). TRUS also has a role in benign conditions such as in the evaluation of treatment options for benign prostatic hyperplasia (BPH) and in some cases of male infertility. This chapter focuses primarily on the most common use of TRUS, namely prostate biopsy for the diagnosis of prostate cancer.

The detection and diagnosis of prostate cancer has benefited greatly from prostate-specific antigen (PSA) screening efforts along with the introduction and refinement of systematic TRUS-guided prostate biopsy techniques. However, these prostate cancer screening efforts are not without controversy (Gomella et al, 2011). When a decision is made to perform a diagnostic prostate biopsy, the 12-core TRUS prostate biopsy is considered the preferred and current standard of care technique (Bjurlin et al, 2013).

TRUS of the prostate was first described by Watanabe and colleagues (1968). The use of digitally directed prostate biopsy, common until the late 1980s, evolved into the expanded clinical use of TRUS-directed prostate biopsies. Improvements in US technology continued with the important introduction of the TRUS-guided systematic sextant (six core), biopsy protocol by Hodge and associates (1989). Concurrent with improved biopsy techniques including the increase in recommended biopsy cores to 12, the use of PSA screening increased the number of men undergoing early prostate cancer screening and prostate biopsy. Current estimates are that up to 1.3 million biopsies are performed annually in the United States alone (Aubry et al, 2013). Given the prevalence of clinically significant and insignificant prostate cancer and the frequency with which TRUS-guided prostate biopsies are performed, significant efforts have been focused on determining the appropriate indications for biopsy, the ideal technique by which to image and perform biopsy of the prostate, and how to best limit complications.

ULTRASONOGRAPHIC ANATOMY OF THE PROSTATE

The prostate lies between the bladder neck and the urogenital diaphragm, just anterior to the rectum, an ideal position to be imaged via TRUS. The prostate gland is traditionally described based on a pathologic zonal architecture. These divisions consist of the anterior fibromuscular stroma, which is devoid of glandular tissue; transition zone (TZ); central zone (CZ); periurethral zone; and peripheral

Prostate Biopsy: Techniques and Outcomes

Advanced and Investigational Techniques for Prostate Biopsy

zone (PZ). Unfortunately, these regions are not visible sonographically as distinct entities (Fig. 109-1).

However, the TZ often may be discernible from the PZ and CZ, particularly in glands with significant BPH. Located posteriorly, the normal CZ and PZ, from which a majority of adenocarcinomas arise, have a homogeneous echogenic appearance, whereas the anteriorly situated TZ is more heterogeneous. Frequently, calcifications along the surgical capsule known as the corpora amylacea highlight the plane between the PZ and TZ (multiple diffuse calcifications are a normal, often incidental ultrasonographic finding in the prostate and represent a result of age rather than a pathologic entity). Larger prostatic calculi associated with symptoms may be related to underlying infection or inflammation and require further evaluation (Geramoutsos et al, 2004).

The prostatic urethra traverses the length of the gland in the midline and thus must be imaged in the sagittal plane to be simultaneously viewed along the entirety of its course (Fig. 109-2A and B). The distended urethral lumen has a hypoechoic appearance, whereas periurethral calcifications may produce a thin echogenic outline. The smooth muscle of the internal sphincter extends from the bladder neck, encircling the urethra to the level of the verumontanum. These muscle fibers may be visualized sonographically as a hypoechoic ring around the upper prostatic urethra, giving it a funneled appearance proximally as it arises from the bladder neck. On reaching the verumontanum the urethra angles anteriorly and runs through the remainder of the gland to exit at the apex of the prostate. This angle gives the prostatic urethra an anteriorly concave appearance when viewed along its entire course in the sagittal plane.

The paired seminal vesicles (SVs) are positioned posteriorly at the base of the prostate (see Fig. 109-2C). They have a smooth, saccular appearance and should be symmetrical. The normal SV measures 4.5 to 5.5 cm in length and 2 cm in width. A cystic SV mass is presumptively benign, whereas a solid lesion has a very small probability of being malignant, especially if the patient has a primary neoplasm elsewhere. Schistosomiasis should be considered when making a differential diagnosis in patients who live in areas where infestation is endemic and have a solid SV mass (Al-Saeed et al, 2003). An absent SV is associated with a 79% ipsilateral renal agenesis. In the transverse plane, the vasa deferentia course just above their ipsilateral SV before diving caudally toward the prostate near the midline. Here they lie just medial to the tapering ipsilateral SV before the two structures fuse to form an ejaculatory duct. The ejaculatory ducts (occasionally seen as a hypoechoic structure) enter the gland posteriorly and empty into the urethra at the verumontanum (see Fig. 109-2C). Their course parallels that of the prostatic urethra distal to the verumontanum.

GRAY-SCALE TRANSRECTAL ULTRASONOGRAPHY

Gray-scale TRUS has become the most common imaging modality for the prostate. Most commonly used for prostate cancer

Figure 109-1. Normal prostate ultrasound images (*top*) with diagrams (*bottom*) at approximately the level of the verumontanum demonstrating zonal anatomy. **A**, Transverse view. **B**, Sagittal view. AFS, anterior fibromuscular stroma; B, bladder; CZ, central zone; DV, dorsal vein complex; EJD, ejaculatory ducts; L, levator muscles; NVB, neurovascular bundle; PZ, peripheral zone; TZ, transition zone; U, urethra.

detection, TRUS also may be used in the evaluation of other conditions, such as infertility (see Chapter 24), or basic prostate volume measurements for interventions such as brachytherapy or in the management of BPH.

Commercially available endorectal probes are available in both side- and end-fire models and transmit frequencies of 6 to 10 MHz. Most modern US machines have optimized self-programming for TRUS and biopsy. Some newer biplane probes provide simultaneous sagittal and transverse imaging modes. Probes provide a scanning angle approaching 180 degrees to allow simultaneous visualization of the entire gland in both the transverse and sagittal planes. Increasing frequency yields increased resolution. As the frequency of the probe is increased, the portion of the image that is in focus (focal range) is closer to the transducer (Kossoff, 2000). The commonly used 7-MHz transducer produces a high-resolution image with a focal range from 1 to 4 cm from the transducer (best for PZ where most cancers arise). Lower frequency transducers (e.g., older 4-MHz transducers) have a focal range from 2 to 8 cm but at lower resolution. Lower frequency transducers improve anterior delineation of large glands, increasing the accuracy of volume measurements, but provide poor internal architecture visualization. Acoustic properties of soft tissue are similar to those of water, but clinically useful US energy does not propagate through air. For this reason, a water-density substance, termed a *coupling medium*, is required. The coupling medium, usually sonographic jelly or lubricant, is placed between the probe and the rectal surface. If the probe is covered with a protective condom, the coupling medium is placed between the probe and the condom, as well as between the condom and the rectal surface.

Various studies have compared the TRUS prostate biopsy prostate cancer detection rates using the end-fire or side-fire probes. Prospective studies have confirmed that there is no significant

difference in positive biopsy rates in the initial or repeat biopsy setting (Raber et al, 2012). However, in this study the side fire transrectal probe is associated with a better patient tolerance.

Machine Settings

The image magnification is adjusted so that most of the prostate is visible without the image being too small to allow detection of abnormalities. In general, the magnification is low during prostate measurements so that the entire gland is seen. During biopsies, magnification is maximal for visualization of needle passage. The ultrasonographer can manually alter the brightness (or gain) slightly with each new patient and occasionally during imaging of different areas within the same prostate. The optimal brightness setting results in a medium-gray image of the normal PZ. This gray tone serves as the reference point for judging lesions as hypoechoic (darker than the normal PZ), isoechoic (similar to the normal PZ), hyperechoic (lighter than the normal PZ), or anechoic (completely black).

Techniques

The complete TRUS evaluation of the prostate includes scanning in both the sagittal and transverse planes to obtain a volume calculation. The CZ and PZ are inspected for hypoechoic lesions and contour abnormalities, and the SVs and vasa deferentia are fully visualized.

Probe Manipulation

Patients are usually scanned in the left lateral decubitus position (see Patient Positioning, later) to examine both the transverse and

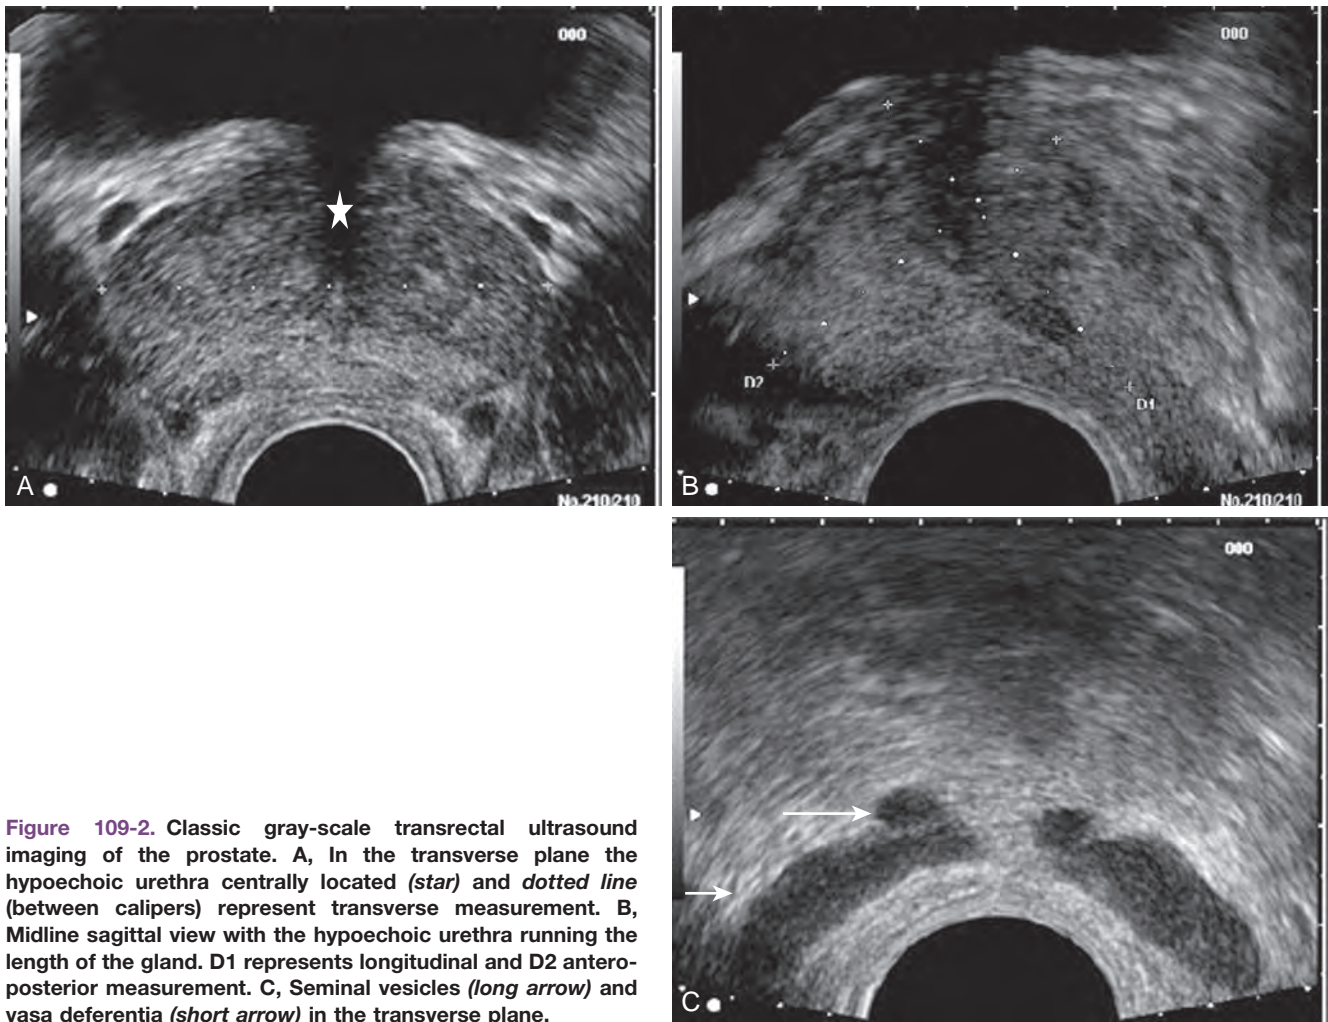

Figure 109-2. Classic gray-scale transrectal ultrasound imaging of the prostate. A, In the transverse plane the hypoechoic urethra centrally located (*star*) and dotted line (between calipers) represent transverse measurement. B, Midline sagittal view with the hypoechoic urethra running the length of the gland. D1 represents longitudinal and D2 anteroposterior measurement. C, Seminal vesicles (*long arrow*) and vasa deferentia (*short arrow*) in the transverse plane.

the sagittal planes. There are two approaches to probe manipulation for transverse imaging (see Fig. 109-2A). With radial and some biplane probes, advancing the probe cephalad into the rectum images the prostate base, the SVs, and the bladder neck. Pulling the probe caudally toward the anal sphincter images the prostatic apex and proximal urethra. Transverse imaging with end-fire, side-fire, and some biplane probes is accomplished by angling the handle of the probe right or left using the anal sphincter as a fulcrum (see Fig. 109-2B). Angling the probe toward the scrotum produces more cephalad images, and angling the probe toward the sacrum produces more caudal images.

There are also two approaches to probe manipulation for sagittal imaging. One method is rotation of the probe. Clockwise rotation yields images of the left side of the prostate, and counterclockwise rotation yields images of the right side. Alternatively, sagittal imaging can be accomplished by angling the probe up or down using the anal sphincter as a fulcrum. In the left lateral decubitus position, angling the handle of the probe down (toward the floor) images the right side of the prostate and angling the handle of the probe up (toward the ceiling) images the left side. Urologists often prefer angling the probe because this method is similar to manipulation of a cystoscope and is less uncomfortable for the patient.

Joint guidelines concerning the reprocessing of equipment used for TRUS biopsy have been published in a joint American Urological Association (AUA)/Society of Urological Nurses and Associates white paper (American Urological Association/Society for Urological Nurses and Associates, 2012).

Volume Calculations

A variety of formulas are used to calculate prostate volume and require measurement of up to three prostate dimensions. In the axial plane, the transverse and anteroposterior (AP) dimensions are measured at the point of widest transverse diameter (see Fig. 109-2A and B). The longitudinal dimension is measured in the sagittal plane just off the midline because the bladder neck may obscure the cephalad extent of the gland (see Fig. 109-2B). Most formulas assume that the gland conforms to an ideal geometric shape: either an **ellipse** ($\pi/6 \times \text{transverse diameter} \times \text{AP diameter} \times \text{longitudinal diameter}$), **sphere** ($\pi/6 \times \text{transverse diameter}^3$), or a **prolate (egg-shaped) spheroid** ($\pi/6 \times \text{transverse diameter}^2 \times \text{AP diameter}$). Despite the inherent inaccuracies that arise from these geometric assumptions, all formulas reliably estimate gland volume and weight, with correlation coefficients greater than 0.90 with radical prostatectomy specimen weights, because 1 cm³ equals approximately 1 g of prostate tissue (Terris and Stamey, 1991). The mature prostate is between 20 and 25 g and remains relatively constant until approximately age 50, when the gland enlarges in many men; the average prostate volume in a 60 to 70 year old is approximately 48 g (Griffiths, 1996).

Planimetry may be employed when a more precise determination of gland volume is required, such as for brachytherapy planning. With the patient in the lithotomy position, the probe is mounted to a stepping device and serial transverse images are obtained at set intervals (e.g., 3 to 5 mm) through the entire length

of the gland. The surface area of each serial image is determined, and the sum of these measurements is then multiplied by total gland length to yield the prostate volume.

Prostate gland volume can be used to calculate derivatives such as the PSA density (PSAD = serum PSA/gland volume). PSAD is a method to differentiate benign versus malignant disease with an elevated PSA and benign digital rectal examination. Higher PSA density values (>0.15 ng/mL/cc) are more suggestive of prostate cancer; lower values suggest BPH. An elevated PSAD has a sensitivity and specificity of 75% and 44%, respectively, for predicting cancer on repeat biopsy (Djavan et al, 2000). Unfortunately, there is high interoperator and intraoperator variability in PSAD determinations, and similar predictive information now can be obtained using serum free-to-total PSA ratio (Djavan et al, 2003).

Cystic Lesions of the Prostate

Cystic prostatic structures are common on TRUS. Simple cysts have the same sonographic appearance as in any other part of the body: they are thin walled, are anechoic, and show acoustic enhancement posterior to the cyst. Prostatic cysts may be congenital or acquired but are rarely clinically significant, regardless of cause.

Congenital prostatic cystic lesions may arise from either müllerian (müllerian duct cysts and prostatic utricles) or wolffian (ejaculatory duct and SV cysts) structures. An enlarged prostatic utricle is a diverticular projection from the posterior urethra at the level of the verumontanum (Cochlin, 2002) and appears as a midline anechoic structure. These are associated with genital anomalies, including hypospadias (most common), ambiguous genitalia, undescended testes, and congenital urethral polyps (Gregg and Sty, 1989). Müllerian duct cysts also appear as midline anechoic lesions that result from failure of the müllerian ducts to fuse with the urethra. They are generally ovoid to pear shaped, with the cyst neck oriented toward the verumontanum. When müllerian duct cysts are present, men should be evaluated for unilateral renal agenesis (McDermott et al, 1993).

Lateral paraprostatic cystic structures include SV and vas deferens cysts (wolffian in origin). Ejaculatory duct cysts are typically small, lie off of the midline, and may accompany ejaculatory duct obstruction/obliteration with azoospermia (Fig. 109-3). SV cysts can be caused by congenital or acquired obstruction of the ejaculatory duct and are associated with cystic renal disease; up to two thirds of men with SV cysts also may have renal agenesis (King et al, 1991). Acquired cysts of the TZ result from hemorrhagic degeneration of BPH nodules (Hamper et al, 1990), whereas those of the outer gland have no proven cause.

Prostate Cancer Imaging on Transrectal Ultrasonography

In early TRUS studies, hypoechoic lesions were considered pathognomonic for prostate cancer. All hypoechoic lesions within the PZ should be noted and included in the biopsy material (Fig. 109-4). The lack of a distinct hypoechoic focus does not preclude proceeding with biopsy, because 39% of all cancers are isoechoic and up to 1% of tumors may be hyperechoic on conventional gray-scale TRUS (Shinohara et al, 1989). A study of almost 4000 men revealed prostate cancer was detected in 25.5% with a hypoechoic lesion and in 25.4% without such a lesion with a per-core distinction of 9.3% for hypoechoic and 10.4% for isoechoic areas for cancer (Onur et al, 2004). Conversely, another study noted that biopsy samples taken when a prostate lesion is identified by TRUS are almost twice as likely to show cancer than when no lesion is visible (Toi et al, 2007). They concluded that the search for and targeting of hypoechoic lesions on TRUS remains important for prostate cancer diagnosis. Other disease processes such as granulomatous prostatitis (Terris et al, 1997), prostatic infarct (Purohit et al, 2003), and lymphoma (Varghese and Grossfeld, 2000) may produce hypoechoic lesions. There is a need to perform a biopsy on hypoechoic lesions, but these lesions are not pathognomonic for cancer as once thought.

Figure 109-3. A hypoechoic midline cystic structure (arrow) arising from the ejaculatory duct is shown in the transverse (A) and sagittal (B) planes and demonstrates through-transmission classic for simple cysts.

Figure 109-4. Classic hypoechoic peripheral zone lesion (dotted line between calipers) in the right mid-gland that transrectal ultrasound-guided biopsy proved to be a Gleason 3 + 3 = 6 adenocarcinoma.

Any focal contour abnormalities along the outer edge of the gland and any asymmetries in echotexture from the PZ of one lobe to that of the other are noted. Extracapsular extension of prostate cancer, although not well visualized if present as a microfocus, is suggested by a focal loss of the typically bright white periprostatic fat.

KEY POINTS: GRAY-SCALE TRANSRECTAL ULTRASONOGRAPHY

- TRUS technology has become a mainstay of many image-guided prostate interventions, including prostate biopsy, brachytherapy, cryotherapy, and high-intensity focused US.
- The classic zonal anatomy of the prostate is not evident on TRUS, but the PZ typically may be distinguished from the TZ, allowing biopsies to be reliably aimed toward the more commonly cancer-bearing PZ.
- Benign cystic lesions of the prostate typically demonstrate thin-walled architecture with sonographic through-transmission and may become symptomatic if infected.
- Several formulas exist for determining prostate volume on TRUS. For highly accurate volume determinations such as for brachytherapy, planimetry using a template is required.
- Hypoechoic foci seen on gray-scale TRUS should be considered suggestive of adenocarcinoma of the prostate and included in the biopsy specimen. However, up to 39% of cancers are not visible on routine gray-scale US imaging.

Transrectal Ultrasonography Appearance after Treatment

External-beam radiation monotherapy therapy usually results in decreased volume by 6 months after treatment. Irradiated prostates are diffusely hypoechoic, with poorly defined anatomy. Large hypoechoic tumors, particularly those not responding to therapy, show little change in echogenicity once irradiated, but smaller foci responding well to therapy tend to become isoechoic (Egawa et al, 1991). TRUS findings in general correlate poorly with pathologic findings and outcomes in irradiated prostates.

Initial postimplantation edema followed by long-term changes occurs with interstitial brachytherapy, as with external-beam radiation therapy (Whittington et al, 1999). With an ideal permanent implant, seeds should be distributed evenly throughout the gland, with periurethral sparing. These seeds are hyperechoic and demonstrate posterior shadowing. The prostate volume declines significantly after treatment, with a 37% size reduction at 1 year after treatment and over 50% reduction 8 years after implantation (Stone and Stock, 2007). This decline appears unaffected by the use of neoadjuvant hormonal therapy.

Androgen ablation with luteinizing hormone–releasing hormone analogues will cause an average 30% volume decrease with androgen deprivation in prostates with and without cancer (Whittington et al, 1999). The decrease ranges up to 60% in large glands and as little as 10% in small glands. Volume decreases by approximately 21% at 6 months using agents such as finasteride (Marks et al, 1997).

Post-radical prostatectomy TRUS is considered normal if there is smooth tapering of the bladder neck to the urethra (Kapoor et al, 1993). Many patients demonstrate a nodule of tissue anterior to the anastomosis, representing the ligated dorsal vein complex (Goldenberg et al, 1992). Any other hyperechoic or hypoechoic lesions or interruptions of the retroanastomotic fat plane are considered suspicious (Kapoor et al, 1993). Hypoechoic lesions have been reported in 75% to 95% of patients with locally recurrent cancer, and color Doppler has been used to improve cancer detection in the prostatic fossa (Tamsel et al, 2006). Patients with detectable PSA who are candidates for salvage radiation therapy were once considered for routine biopsy of the anastomotic area. Biopsy of the anastomotic region with PSA-indicated recurrence in the absence of a palpable nodule is not usually informative (Scattoni et al, 2004). However, biopsy of an abnormality seen on TRUS, even with a normal digital rectal examination, can be diagnostic of locally recurrent disease (Naya et al, 2005).

Transrectal Ultrasonography and Other Malignancies

Prostatic involvement with transitional cell carcinoma (TCC) from the bladder is generally not detectable by TRUS, but 71% of

prostatic stromal TCC lesions are hypoechoic. Prostatic TCC detected by TRUS must be confirmed by biopsy because granulomas resulting from instillation of bacillus Calmette-Guérin are common in patients with urothelial carcinoma and also are hypoechoic (Terris et al, 1997).

Extension to the prostate from the bladder, or urethral squamous cell carcinoma (SCC), is much more common than is primary prostatic SCC. Prostatic SCC appears as an irregular, anterior mass demonstrating relative hyperechogenicity (Terris, 1999).

Adenoid cystic/basal cell carcinoma of the prostate is rare but potentially fatal. Histologically, cribriform or adenoid cystic patterns predominate. Numerous cystic glands give this tumor an unusual appearance on TRUS, characterized by multiple, evenly distributed, small anechoic cysts (Iczkowski et al, 2003).

Prostatic sarcoma TRUS appearance is typified by an irregular, hypoechoic mass with an anechoic area consistent with necrosis (Terris, 1998). The echogenicity of rhabdomyosarcoma is similar to that of normal prostate tissue. Hematologic and lymphoid malignancies involving the prostate are generally not visualized with TRUS (Terris and Freiha, 1998). Biopsy specimens may demonstrate a lymphocytic infiltrate, but this is often attributed to chronic inflammation if no suspicion of nonprostate malignancy exists.

PROSTATE BIOPSY: TECHNIQUES AND OUTCOMES

Indications for Prostate Biopsy

A detailed discussion of the controversy concerning screening asymptomatic men for prostate cancer is discussed elsewhere (see Chapter 111). Before TRUS improvements and PSA testing became widespread, clinicians relied mainly on digital rectal examination to establish a suspicion of prostate cancer and performed digitally directed lesional biopsies. Today PSA-based screening of asymptomatic men has resulted in the adaptation of TRUS biopsy as the standard of care when prostate biopsy is used to identify prostate cancer (Bjurlin et al, 2013). In general the TRUS without a biopsy has little utility in the evaluation of a patient for prostate cancer. Overall it is estimated that an initial prostate biopsy carries a 30% rate of detecting prostate cancer. Fine-needle aspiration biopsy is no longer considered state-of-the-art in the diagnosis of prostate cancer (Heidenreich et al, 2014).

Early prostate cancer detection was markedly improved by PSA-based screening programs. These initiatives increased the rate of organ-confined and potentially curable disease (Catalona et al, 1993). The improvements led to the unintended consequence of the overdiagnosis and overtreatment of clinically insignificant cancers in many men. Historically, many clinicians would recommend prostate biopsy once a patient's serum PSA level rose above 4.0 ng/mL. Subsequent data from the Prostate Cancer Prevention Trial demonstrated that there is no safe PSA threshold that can rule out prostate cancer in any age range (Thompson et al, 2005). When examining men whose serum PSA level was 4.0 ng/mL or less, significant numbers were diagnosed with prostate cancer at all PSA levels, with an overall prostate cancer detection rate of 15% for all men with a PSA level less than 4.0 ng/mL and nearly 15% having a Gleason score of 7 or greater (Thompson et al, 2004).

Clinical trials that have attempted to provide an answer to the benefits of PSA screening have only added to the controversy (Gomella et al, 2011). Results from the European Randomized Screening for Prostate Cancer (ERSPC), demonstrated a net benefit, whereas the U.S.-based Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, showed no benefit on prostate cancer-specific survival (Hayes and Barry, 2014). Recommendations by organizations vary greatly on screening asymptomatic men for prostate cancer, with some supporting screening based on informed decision making and others rejecting the performance of PSA-based screening in an asymptomatic man (Gomella et al, 2011; Hayes and Barry, 2014). Considerations concerning overall health, age of the patient, family history, therapeutic options, wishes of the patient, and other risk factors all need to be considered in recommending prostate biopsy. In addition, concerns are growing over the potential

morbidity and mortality of prostate biopsy (Zlotta and Nam, 2012). A variety of online nomograms are available that may help with decision making (Nguyen and Kattan, 2013).

Organizations such as the AUA recommend shared decision making for men 55 to 69 years of age considering PSA-based screening, a target age group for whom benefits may outweigh harms (Carter et al, 2013). Outside this age range, the AUA recommends that PSA-based screening as a routine could not be recommended based on the available evidence. Most organizations have abandoned absolute PSA level cutoff values for prostate biopsy and are relying increasingly on risk stratification approaches and changes in PSA level over time. Men at elevated risk for having prostate cancer are those older than 50 years of age, or have a family history of prostate cancer and are older than 45 years, or African-Americans, or men with a PSA level greater than 1 ng/mL at 40 years and greater than 2 ng/mL at 60 years (Heidenreich et al, 2014).

Adjuncts to serum PSA testing have been advocated to improve the performance characteristics of PSA for prostate cancer detection, including free-to-total PSA ratio, PSA velocity, and PSAD, but are not uniformly reliable (Heidenreich et al, 2014). The National Comprehensive Cancer Network (NCCN) (2012) advocates the use of some of these PSA derivatives in the decision to perform TRUS biopsy. In the patient appropriate for prostate cancer screening they recommend TRUS prostate biopsy in the following situations: positive digital rectal examination regardless of PSA level; PSA 4 to 10 ng/mL based on patient risk benefit; PSA level 2.5 ng/mL or less and PSA velocity 0.35 ng/mL or greater per year; PSA level 2.6 to 4.0 ng/mL; PSA level 4.0 ng/mL or greater, especially if the free PSA level is 10% or less. As recommended by the NCCN, the presence of nodules on digital rectal examination usually should prompt TRUS biopsy regardless of PSA levels. In a recent study, 14% of cancers were diagnosed based on digital rectal examination alone (Okotie et al, 2007). However, the American Cancer Society guidelines now suggest that the prostate cancer screening can be performed with or without a rectal examination (Smith et al, 2014). In addition to an initial prostate biopsy, there are several indications for repeat prostate biopsy, as noted in Box 109-1.

The use of newer molecular techniques such as urinary determination of PCA3 to identify men at risk for a positive biopsy finding is evolving. Several studies have suggested that PCA3 provides supplemental information in determining the need for repeat prostate biopsy (Gittelman et al, 2013). In the largest study of this urinary marker to date, the mean PCA3 was 27.2 and 52.5 for patients without and with cancer, respectively, suggesting this is a useful tool in identifying patients at risk for prostate cancer before initial biopsy (Chevli et al, 2014).

Contraindications to Prostate Biopsy

Significant coagulopathy, severe immunosuppression, and acute prostatitis are all contraindications to prostate biopsy. With painful anorectal conditions or anal stenosis, prostate biopsy under general or regional anesthesia should be considered.

Preparing Patients for Biopsy

Patients should be informed of the risks and benefits of the procedure and informed consent obtained. Herbal supplements also should be discontinued because many contain undeclared agents. Low-dose aspirin does not need to be discontinued (Giannarini et al, 2007). Anticoagulant therapy (warfarin, clopidogrel, etc.) should be stopped 7 to 10 days before prostate biopsy. The novel oral anticoagulants apixaban, dabigatran, and rivaroxaban are stopped 2 to 5 days before (Culkin et al, 2014). Rivaroxaban may increase stroke risk if stopped; therefore bridging with some other anticoagulant such as heparin is recommended. For those patients with underlying coagulopathy or on warfarin, prostatic biopsy should not be performed until the international normalized ratio has been corrected below 1.5 if the patient has low risk for a thromboembolic event. Because of the higher risk for thromboembolic events (e.g., mechanical valves) on warfarin, bridging

BOX 109-1 Commonly Cited Indications for Transrectal Ultrasonography Alone and Transrectal Ultrasonography with Initial and Follow-up Prostate Biopsy

TRANSRECTAL ULTRASONOGRAPHY WITHOUT PROSTATE BIOPSY

- Treatment planning volume measurements: Brachytherapy, cryotherapy, benign prostatic hyperplasia therapy (e.g., transurethral microwave thermotherapy, radiofrequency ablation)
- Volume measurement during hormonal downsizing for external-beam radiation therapy or brachytherapy
- Placement of fiducial or radiofrequency markers for external-beam radiation therapy
- Evaluation of azoospermia: Ejaculatory duct cysts, seminal vesicle cysts, etc.
- Therapeutic aspiration or unroofing of prostatic cysts; drainage of prostatic abscess

INITIAL PROSTATE BIOPSY

- Initial diagnosis of prostate cancer based on informed decision making in an asymptomatic patient (based on PSA and patient-specific risk factors; see text)
- Suspicious digital rectal examination findings/prostate nodule (5%-30% cancer risk)
- To diagnose prostate cancer with symptoms suggestive of prostate cancer
- To diagnose prostate cancer with findings suggestive of metastatic disease (bone lesions and/or adenopathy)
- In the setting of prostate cancer detected on routine, transurethral resection of the prostate performed for presumed benign disease

REPEAT PROSTATE BIOPSY

- Rising and/or persistently elevated PSA
- Atypical small acinar proliferation (40% cancer risk)
- Extensive (multiple biopsy sites) with PIN (20%-30% cancer risk) (NOTE: isolated high-grade PIN is no longer considered an indication for repeat biopsy)
- Positive urinary PCA3 or other newer genomic tests such as Confirm MDx* methylation assay
- Suspicious lesion on prostate magnetic resonance imaging
- Differentiate local recurrence versus systemic disease with PSA recurrence after local ablative therapy

FOLLOW-UP PROSTATE BIOPSY

- Active surveillance follow-up protocol

PIN, prostatic intraepithelial neoplasia; PSA, prostate-specific antigen.

*Confirm MDx, MDxHealth, Irvine, CA.

Modified from Heidenreich et al, 2014; Thomsen et al, 2014; and Gomella and Amirian, 2015.

anticoagulation with unfractionated heparin or low-molecular-weight heparin is suggested.

A small amount of urine in the bladder is useful before the biopsy. This helps facilitate the examination by demonstrating the prostatic bladder junction.

Antibiotic Prophylaxis

An increasing frequency of complications has been recently noted with most postbiopsy hospitalizations resulting from infectious causes (Loeb et al, 2013). This has placed a renewed focus on antibiotic prophylaxis and other strategies to reduce postbiopsy

infectious complications. Unlike other lower urinary tract procedures, antimicrobial prophylaxis is recommended for all patients undergoing prostate biopsy, irrespective of risk factors. The 2014 updated latest AUA best practice policy recommended antibiotics for prostate biopsy include fluoroquinolones; first-, second-, and third-generation cephalosporins; and aminoglycoside (level of evidence, Ib) (American Urological Association, 2014). The 2014 update added oral trimethoprim-sulfamethoxazole as a prophylactic agent, and when using intramuscular or intravenous aminoglycoside or aztreonam as an alternative agent, metronidazole or clindamycin is no longer required. The intramuscular route is acceptable for all recommended agents, and the oral route is recommended only for quinolones (Table 109-1). For patients at risk for developing endocarditis or infection of prosthetic joints, pacemakers, and automated implanted cardiac defibrillators, prophylaxis should consist of intravenous ampicillin (vancomycin, if penicillin allergic) and gentamicin preoperatively, followed by 2 to 3 days of an oral fluoroquinolone. A 2011 Cochrane review on prophylaxis

for TRUS prostate biopsy demonstrated a reduction in bacteriuria, bacteremia, fever, urinary tract infection (UTI), and hospitalization with antibiotics compared to placebo or no treatment (Zani et al, 2011). There was no definitive evidence demonstrating superiority of longer course or multiple doses compared to a shorter course or single any-dose protocols.

As a result of the increasing resistance patterns to fluoroquinolones there has been recent interest in using individual culture data to guide antibiotic prophylaxis by using a rectal swab culture before biopsy (Taylor et al, 2012). The presence of fluoroquinolone-resistant organisms on a rectal swab culture has not always translated into clinical infection. In one multi-institutional study, rectal swab cultures immediately before biopsy in 136 men who received ciprofloxacin and gentamicin for prophylaxis had fluoroquinolone-resistant *Escherichia coli* in 22% of cultures (Liss et al, 2011). Only 5 (4%) patients had postbiopsy fever, and only 1 of them had a positive rectal screen for resistant *E. coli*. Although this result might have been prevented through targeted prophylaxis, the low overall complication rate raises questions about the cost-effectiveness of such a strategy. Additional studies are needed to define culture-directed therapy and compare its cost-effectiveness to empirical therapy based on local susceptibility patterns (Loeb, 2013).

TABLE 109-1 American Urological Association 2014 Best Practice Policy Recommended Antibiotics for Routine Prostate Biopsy*

DRUG	DOSAGE
FLUOROQUINOLONES†	
Levofloxacin	500 mg PO single dose
Ciprofloxacin	500 mg PO q12h
Ofloxacin	400 mg PO q12h
AMINOGLYCOSIDES‡	
Gentamicin	5 mg/kg IV single dose
Tobramycin	5 mg/kg IV single dose
Amikacin	15 mg/kg IV single dose
FIRST-GENERATION CEPHALOSPORINS	
Cephalexin	500 mg PO q6h
Cephadrine	500 mg PO q6h
Cefadroxil	500 mg PO q12h
Cefazolin	1 g IV q8h
Cefaclor	500 mg PO q8h
Cefprozil	500 mg PO q12h
Cefuroxime	500 mg PO q12h
Cefoxitin	1-2 g IV q6h
THIRD-GENERATION CEPHALOSPORINS	
Ceftizoxime	1 g IV q8h
Ceftazidime	1 g IV q12h
Ceftriaxone	1-2 g IV single dose
Cefotaxime	1 g IV q8h
ALTERNATIVE AGENTS	
Aztreonam	1-2 g IV q8h
Trimethoprim-sulfamethoxazole	1 double-strength tablet PO q12h

*The recommended duration of antimicrobial prophylaxis is 24 hours or less (level of evidence: Ib).

†Fluoroquinolones are associated with an increased risk for tendinitis and tendon rupture.

‡Aztreonam can be substituted for aminoglycosides in patients with renal insufficiency.

Modified from American Urological Association. Best practice policy statement on urologic surgery antimicrobial prophylaxis, <<http://www.auanet.org/content/media/antimicroprop08.pdf>>; 2008 (revised August 2011, updated January 1, 2014) [accessed 04.05.14].

Cleansing Enema

We routinely have patients self-administer a cleansing enema at home before biopsy. **This practice decreases the amount of feces in the rectum, thereby producing a superior acoustic window for prostate imaging.** The enema's effect on reducing infections is debatable. However, many clinicians may elect not to use an enema because this may allow more spontaneous performance of a prostate biopsy.

Analgesia

TRUS-guided infiltration anesthesia near the nerve bundles with local anesthetic can provide excellent pain control (Berger et al, 2003; Trucchi et al, 2005). A local prostatic block is achieved using 1% to 2% lidocaine, a long spinal needle (7-inch, 22-gauge), and TRUS guidance along the biopsy channel of the transducer. Multiple variations exist for the infiltration of local anesthetic for transrectal biopsy (Ismail and Gomella, 2013). We found that injecting 5 mL of lidocaine at the level of the SVs near the bladder base at the hyperechoic fat pad that demarcates the junction of the SVs and the prostate bilaterally produces an excellent block. Other approaches include infiltration of 10 mL starting at the junction of the SVs and infiltrating along the lateral aspect of the prostate from base to apex. **Direct infiltration into the prostate (intraprostatic injection) can augment the anesthetic benefit seen with periprostatic injection (Cam et al, 2008).** Saturation biopsy schemes may require up to 22 mL of 1% lidocaine. Caution is needed, however, to avoid direct intravascular injection because of the risk for systemic lidocaine absorption. Intrarectal (topical) instillation of a local anesthetic is inferior to periprostatic infiltration (Heidenreich et al, 2014). **Local anesthesia for transperineal biopsies also should include infiltration of the skin and subcutaneous tissues of the perineum initially.** US guidance then may be employed to aid infiltration of deeper tissues along the anticipated tracts of the biopsy needle.

Patient Positioning

Patients are usually placed in the left lateral decubitus position with knees and hips flexed 90 degrees. An armboard attached parallel to the table and a pillow between the knees helps maintain this position. The buttocks should be flush with the end of the table to allow manipulation of the probe and biopsy gun without obstruction. If necessary, the right lateral decubitus or lithotomy position can be used. **The lithotomy position is used by some clinicians and is preferred for transperineal biopsies, brachytherapy treatment planning, or placement of fiducial gold markers for external-beam therapy (Dehnad et al, 2003).**

Figure 109-5. Various reported systematic biopsy schemes. Base is at the top of figure, apex is at bottom. A, Sextant biopsy scheme originally proposed by Hodge and associates (Hodge et al, 1989). B, The 10-core biopsy (Presti et al, 2000). C, The 12-core, or double-sextant, biopsy. This is the currently recommended sequence endorsed by the American Urological Association (Bjurlin et al, 2013). D, The 13-core, 5-region biopsy (Eskew et al, 1997).

Transrectal Prostate Biopsy Techniques

An initial digital rectal examination should be performed to evaluate for any prostate nodularity or anal pathologic processes. The prostate volume is determined, and imaging of the prostate in both the transverse and sagittal planes is begun. The examination usually starts at the base of the gland and extends to the apex. Most modern US units are automatically set for optimal prostate viewing, and the TRUS gray-scale examination of the prostate is conducted as previously described, noting the location and characteristics of any lesions (i.e., hypoechoic, hyperechoic, calcifications, contour abnormalities, cystic structures).

A spring-driven 18-gauge needle core biopsy device or biopsy gun that can be passed through the needle guide attached to the US probe is most often used. Most US units provide best visualization of the biopsy needle path in the sagittal plane. Images are typically superimposed with a ruled puncture path that corresponds to the needle guide of the TRUS unit. The biopsy gun advances the needle 0.5 cm and samples the subsequent 1.5 cm of tissue with the tip extending 0.5 cm beyond the area sampled (Kaye, 1989). Therefore, when sampling the PZ, the needle tip may be placed 0.5 cm posterior to the prostate capsule before firing; advancing the needle to or through the capsule can result in sampling of more anterior tissue, missing the most common location of cancers. Avoiding adjustment of the probe position while the biopsy needle is in contact with the rectal surface and applying pressure with the probe to compress the rectal mucosa before biopsy can minimize rectal bleeding. Pressing the probe against the rectum also minimizes the discomfort of the biopsy needle traversing the rectal mucosa, similar to pulling the skin tight to minimize the discomfort of phlebotomy.

The biopsy sample is typically placed in 10% formalin or per local protocol. An AUA white paper recently outlined the recommended processing of prostate biopsy samples, and the review did not provide compelling evidence that individual site-specific labeling of cores benefits clinical decision making regarding the management of prostate cancer (Bjurlin et al, 2013). The paper recommends packaging no more than two cores in each jar to avoid reduction of the cancer detection rate through inadequate tissue sampling.

Sextant Biopsy

The original sextant biopsy scheme (one core from the base, mid, and apex bilaterally) significantly improved cancer detection over digitally directed biopsy of palpable nodules and US-guided biopsy of specific hypoechoic lesions (Hodge et al, 1989). Taken in the parasagittal plane these cores sampled a portion of the PZ but also included a significant amount of tissue from the TZ. Subsequent studies of radical prostatectomy specimens demonstrated that the vast majority of adenocarcinomas arise in the posterolateral PZ (McNeal et al, 1988), thus explaining some of the false-negative results of standard sextant biopsy (Eskew et al, 1997).

Extended-Core Biopsy Techniques

Modifications to the standard sextant biopsy scheme initially focused on the importance of laterally directed cores (Terris et al, 1992). Numerous studies have shown improved cancer detection rates by incorporating additional laterally directed cores into the standard systematic sextant technique. At present, six cores are considered inadequate for routine prostate biopsy for cancer detection. Figure 109-5 depicts the originally proposed sextant technique and several common extended-core biopsy strategies.

Today the extended 12-core systematic biopsy that incorporates apical and far-lateral cores in the template distribution allows maximal cancer detection and avoidance of a repeat biopsy while minimizing the detection of insignificant prostate cancers. This approach has been endorsed in a recent AUA white paper (Bjurlin et al, 2013, 2014). Although increasing the cores from 6 to 12 results in a significant increase in cancer detection rate, increasing the number of cores to 18 or 21 (often termed *saturation biopsy*) as an initial biopsy strategy does not appear to result in a similar increase. However, a series of men from the Cleveland Clinic whose initial biopsy was by a transrectal saturation technique were less likely to have cancer identified during repeat biopsy. Further, if prostate cancer was diagnosed after negative initial saturation biopsy, it was much more likely to be clinically insignificant (Li et al, 2014). Their findings suggest saturation biopsy may be less likely to miss clinically significant cancer during initial prostate biopsy. At present, saturation biopsy is more likely to be considered in the setting of a prior negative biopsy (see later discussion).

TZ and SVs are not routinely sampled because these regions have been shown to have consistently low yields for cancer detection at initial biopsy (Epstein et al, 1997), but TZ and anteriorly directed biopsies may occasionally prove necessary to diagnose prostate cancer in those patients with persistently elevated PSA levels and prior negative biopsies (Mazal et al, 2001). However, there may be a limited role for TZ biopsies in men with gland size of more than 50 mL, with an additional yield of 15% cancer detection in these larger prostates (Chang et al, 1998). Today, magnetic resonance imaging (MRI) is often used to detect and guide biopsies of these anterior tumors that may escape standard TRUS prostate biopsy (Volkin et al, 2014). SV biopsy is not routinely performed unless there is a palpable abnormality, with some authors recommending SV biopsy when the PSA value is greater than 30 or if brachytherapy is being considered (Gohji et al, 1995).

Repeat and Saturation Prostate Biopsy

The dilemma of a patient who has had one or more negative prostate biopsies yet continues to have an elevated PSA value or abnormal digital rectal examination of concern for prostate cancer is a common clinical scenario. Often these patients have undergone multiple biopsies despite the well-documented decline in cancer detection with each successive biopsy (Djavan et al, 2003). Keetch

and coworkers (1994) reported an initial positive biopsy rate of 34% in 1136 men from their PSA-based prostate cancer screening program. Cancer detection rates then fell to 19%, 8%, and 7% on biopsy 2, 3, and 4, respectively. These findings were confirmed by results from an initial ERSPC series. In this cohort of 1051 men with PSA values between 4.0 and 10.0 ng/mL the initial cancer detection rate with sextant biopsy was 22%. Positive cores were then found in only 10%, 5%, and 4% of patients on subsequent biopsies 2, 3, and 4, respectively (Djavan et al, 2001a). In a contemporary follow-up from the same ERSPC study, positive predictive values (PPVs) for men without previous biopsy remained equal throughout the three subsequent screenings (25.5%, 22.3%, and 24.8%, respectively) (Bokhorst et al, 2012). Conversely, PPVs for men with a previous negative biopsy result dropped significantly (12.0% and 15.2% at the second and third screening, respectively). In men with and without previous biopsy, the percentage of aggressive prostate cancers (clinical stage >T2b, Gleason score ≥ 7) decreased after the first round of screening from 44.4% to 23.8% in the second round and 18.6% in the third. Repeat biopsies accounted for 24.6% of all biopsies, but yielded only 8.6% of all aggressive cancers.

The diminishing returns coupled with improved cancer detection rates on initial biopsy with extended-core protocols have led some researchers to examine saturation biopsy techniques (i.e., >12-core biopsy) in this difficult subset of patients with negative previous biopsy results. In a study of 57 men with an average of two prior negative sextant biopsies, a cancer detection rate of 30% was obtained, with an average of 22.5 cores per patient (Borboroglu et al, 2000). Similar protocols from the Mayo Clinic (Stewart et al, 2001) and Toronto (Fleshner and Klotz, 2002) demonstrated improved cancer detection rates. **A drawback to these techniques is that additional anesthetic requirements often require these saturation biopsies to be performed in a hospital setting.** More recent reports question the benefit of a follow-up saturation biopsy scheme, considering the attendant increased cost and potential morbidity. In a reassessment of their previous work on saturation biopsy, investigators at the Mayo Clinic performed a large prospective study of standard systematic and saturation biopsy techniques and did not find a significant increase in prostate cancer detection (Ashley et al, 2008).

The use of a second prostate biopsy in all cases of a negative finding on initial biopsy appears justified if there are concerns about undetected cancer. Third and fourth repeat biopsies, however, should be obtained only in selected patients with high suspicion for cancer and/or poor prognostic factors on the first or second biopsy (Djavan et al, 2005). **When performing repeat biopsy, attention should be placed on the apex, which may not be adequately sampled by the TRUS biopsy approach.**

The role of additional modalities continues to evolve in the setting of repeat biopsy. Techniques such as contrast-enhanced TRUS (CE-TRUS) and MRI targeted approaches discussed later in this chapter will have an impact on the approach to negative biopsy in the future (Halpern et al, 2005; Volkin et al, 2014). The use of newer molecular and genomic assays also will have an impact on the decision making in the future in the setting of a negative prostate biopsy (Gittelman et al, 2013; Partin et al, 2014; Gomella and Amirian, 2015).

Transperineal Prostate Biopsy

Transperineal biopsy offers an approach to the prostate in those patients lacking a rectum (e.g., surgical extirpation, congenital anomaly). The potential for reduced infectious and other complication rates and improved identification of apical tumors are now considered benefits to the transperineal biopsy technique (Chang et al, 2013). The main trade-off appears to be the need for more extensive anesthesia when using the perineum to approach the prostate.

The patient is positioned in dorsal lithotomy with the perineum shaved and prepped as for a sterile surgical procedure. An end-fire US transducer is used. Despite significant limitations in

visualization via this technique compared with TRUS, the prostate can and should be imaged in both the coronal and sagittal planes with calculation of the gland volume. Via the transperineal window, focal PZ hypoechoic lesions are difficult to visualize, as are the SVs. The urethra will appear as a hypoechoic midline structure and may be readily identified by following the corpus spongiosum proximally from the base of the penis. Once the boundaries of the gland have been clearly delineated in the coronal plane, a minimum of six cores should be taken, three from either side of midline.

The diagnostic yield of transperineal US-guided prostate biopsy was compared with that of TRUS-guided biopsies in a routine biopsy setting (Vis et al, 2000). By using radical prostatectomy specimens with TRUS biopsy-detected prostate cancer, simulated transperineal biopsies were performed and transrectal biopsies were repeated. Significantly, 82.5% of the known tumors were detected with the longitudinal transperineal approach versus 72.5% of cancer detection with repeat transrectal biopsy. The authors postulate that the longitudinal orientation of their cores allows more efficient sampling of the PZ, thereby improving cancer detection.

By using this approach in the repeat biopsy setting, Pinkstaff and associates (2005) obtained a mean of 21.2 cores (range, 12 to 41) in 210 men using a template perineal biopsy. The transperineal approach enhanced identification of TZ cancers not detected by previous transrectal prostate biopsy in high-risk patients. However, a Japanese randomized trial comparing transrectal and transperineal techniques for initial prostate biopsy, the cancer detection rate was similar for both, with higher complications noted in the transperineal approach (Hara et al, 2008). Therefore the authors concluded that transrectal prostate biopsy should be the preferred technique for initial prostate biopsy. An increased rate of urinary retention is noted for the transperineal approach, especially in the saturation biopsy setting (Moran et al, 2006). More recently, numerous benefits have been cited: possible improved cancer detection rates, improved anterior and apical sampling, reduced false-negative results, and reduced risk for underestimating disease volume and grade. **The increasing incidence of antimicrobial resistance and patients with diabetes mellitus who are at high risk for sepsis also favors transperineal biopsy as a sterile alternative to standard TRUS-guided biopsy (Chang et al, 2013).** The detection rate of anterior zone prostate cancer in patients undergoing initial and repeat transperineal prostate biopsy is increased by 10% in another series (Pepe et al, 2014).

The technique of three-dimensional (3D) transperineal mapping biopsy has been reported (Barqawi et al, 2011). This uses a transperineal brachytherapy template and can include over 50 mapping biopsy cores based on the size of the gland, far more than obtained with saturation biopsy. It may provide additional information and identify higher risk disease in men thought to have low-risk disease on standard 10- to 12-core TRUS biopsy. Further investigations are needed to establish the utility of this approach.

Transurethral Prostate Biopsy

Transurethral resection biopsy was once advocated for the diagnosis of TZ cancers or after negative TRUS sampling. In contemporary series, solitary TZ cancers, without concomitant PZ tumors, are estimated to occur in less than 5% of patients with prostate cancer (Pelzer et al, 2005). **With improved TRUS techniques including local anesthesia, the TZ can be adequately sampled, and the value of transurethral biopsy has been questioned for the vast majority of patients (Bratt, 2006).** In addition, MRI has shown utility in the identification of TZ and anterior prostate cancers and is particularly effective when used in a TRUS/MRI fusion biopsy system, further limiting the utility of the transurethral biopsy (Volkin et al, 2014).

Risks and Complications of Prostate Biopsy

Although generally considered a safe procedure, TRUS prostate biopsy can be associated with complications. The incidence of serious complications requiring hospitalization is relatively low (<1%). In a Canadian study of over 41,000 men with negative

biopsy results, the 30-day hospital admission rate after prostate biopsy increased from 1.0% in 1996 to 4.1% in 2010 (Nam et al, 2013). The majority of hospital admissions (72%) were related to bacterial infections. An overview of common complications include hematospermia, hematuria, rectal bleeding, prostatitis, fever greater than 101.3° F, epididymitis, urinary retention, and other complications requiring hospitalization (Heidenreich et al, 2014). Large screening series such as the PLCO and ERSPC show that prostate biopsy is not associated with excess mortality, and the overall rate of infectious complications is less than 1% (Pinsky et al, 2014). This low overall absolute risk for serious biopsy-related complications suggests that a fear of complications alone should not deter healthy men with a long life expectancy from pursuing early prostate cancer detection.

Postbiopsy Infections

Most infectious complications after TRUS biopsy are limited to symptomatic UTI and low-grade febrile illness, which can be readily treated with oral or intravenous antibiotics; however, increasing reports of hospitalizations and fatal sepsis after prostate biopsy are being reported (Wagenlehner et al, 2014). The contemporary risk for hospitalization for infectious complications ranges from 0.6% to 4.1%, with the reported incidence of UTI from 2% and 6% (Nam et al, 2013; Bjurlin et al, 2014). Although hospitalizations for sepsis are increasing after prostate biopsy, data suggest that the mortality in this group was not excessive when compared to that of other similar systemic infections (Loeb, 2013). Sepsis is the clinical syndrome characterized by a systemic inflammatory reaction to an infectious process; the symptoms are nonspecific and may include fever, hypothermia, tachypnea, tachycardia, altered mental status, and hypotension (American Urological Association/Society for Urological Nurses and Associates, 2012). Any patient who presents with a fever after a prostate biopsy should be assessed for the presence of sepsis. Septic shock refers to acute circulatory failure (hypotension) that persists despite adequate fluid resuscitation.

A main factor for severe infection seems to be the presence of fluoroquinolone-resistant fecal bacteria possibly due to use of these agents widely in health care settings, as well as other sources such as the food supply (Heuer et al, 2009). The use of targeted prophylaxis after rectal flora swabbing and culture has been shown to have some utility compared with empirical antibiotic prophylaxis in some series. Various bowel preparations are under investigation, but none have been shown to significantly reduce infection rates. As discussed previously, transperineal prostate biopsy is currently being evaluated to reduce infections, with limited data supporting this approach at present (Grummet et al, 2014).

Organisms reported to result in sepsis are predominantly *E. coli*, with high rates of resistance to fluoroquinolones, trimethoprim-sulfamethoxazole, and ampicillin. However, all isolates in this series were susceptible to second- and third-generation cephalosporins, amikacin, and carbapenems (e.g., imipenem, meropenem) (Loeb, 2013). Risk factors for prostate biopsy-related infection include: nonwhite race, increased number of comorbidities, diabetes mellitus, prostate enlargement, foreign travel, and recent antibiotic use. Another risk factor was the number of previous biopsies. The number of previous prostate biopsies significantly associated with an increased risk for infectious complications in men on an active surveillance protocol (Ehdaie et al, 2014). Familiarity with local antibiotic resistance patterns can aid in rapid treatment of symptomatic infection after prostate biopsy.

Bleeding

Even with normal coagulation parameters, bleeding is the most common complication seen after prostate biopsy. Prostate biopsy is considered to be intermediate risk for bleeding (Naspro et al, 2013). As noted, any potential medications that can alter coagulation parameters, including herbal remedies, should be held for 5 to 7 days before biopsy and those on warfarin managed as noted. Two

large European screening programs noted hematuria in 23% to 63% of men after sextant biopsy, with clot retention developing in 0.7% (Djavan et al, 2001b; Raaijmakers et al, 2002). Rectal bleeding is common and seen in 2.1% to 21.7% of patients (Enlund and Varenhorst, 1997; Djavan et al, 2001b). Rectal bleeding is typically minor and readily controlled with direct pressure by the US probe or digitally; persistent brisk blood loss per rectum may require more aggressive intervention for control. Additional measures include rectal tamponade with an inflated condom, anoscopy/colonoscopy with injection of epinephrine and polidocanol or use of sclerotherapeutic agents, angiography with embolization, transrectal exploration, and suturing (American Urological Association/Society for Urological Nurses and Associates, 2012).

Hematospermia, commonly seen after biopsy, is of minimal clinical importance but can cause significant anxiety if not discussed at the time of biopsy; 9.8% to 50.4% of men experience some blood in their ejaculate (Djavan et al, 2001b; Raaijmakers et al, 2002). In one study the mean duration of hemospermia was 4 (± 1.4) weeks, with the number of ejaculations before resolution at six (± 5.6). No factors predicted the duration of hemospermia (Abdelkhalek et al, 2013).

Other Complications

Excessive anxiety and discomfort from the endorectal probe may produce a moderate or severe vasovagal response in 1.4% to 5.3% of patients (Rodriguez and Terris, 1998; Djavan et al, 2001b) and may require termination of the procedure. Placing the patient in the Trendelenburg position and use of intravenous hydration usually resolve these symptoms, with further intervention as clinically indicated.

Acute urinary retention requiring temporary catheterization develops in 0.2% to 0.4% of patients after TRUS biopsy (Enlund and Varenhorst, 1997; Raaijmakers et al, 2002). Men with significantly enlarged glands and those with significant lower urinary tract symptoms, such as those with a high International Prostate Symptom Score (IPSS), are more prone to develop retention (Rodriguez and Terris, 1998; Raaijmakers et al, 2002). Any prostate biopsy may increase the IPSS, but this appears to be transient.

The effects of prostate biopsy on erectile dysfunction have been incompletely characterized. Very early studies suggested that erectile dysfunction after TRUS biopsy was due to damage to the neurovascular bundles (Zisman et al, 2001). Since that time the studies have been conflicting, with a more recent study suggesting erectile dysfunction is more pronounced in men who had a diagnosis of prostate cancer than in those who were cancer free (Helfand et al, 2013).

ADVANCED AND INVESTIGATIONAL TECHNIQUES FOR PROSTATE BIOPSY

Color and Power Doppler Transrectal Ultrasonography

Color Doppler imaging is based on the frequency shift in the reflected sound waves from the frequency of insonation and thus depicts the velocity of blood flow in a directionally dependent manner (Fig. 109-6A). Color assignment is based on the direction of blood flow related to the orientation of the transducer receiving the signal; flow toward the transducer is depicted in shades of red and flow away in shades of blue; the color is not specific for arterial or venous flow. Power Doppler imaging (also known as enhanced color Doppler, color amplitude imaging, or color angiography) uses amplitude shift to detect flow in a velocity and directionally independent manner (Bude and Rubin, 1996) (see Fig. 109-6B). The advantages of power Doppler imaging are its ability to detect slower flow and less reliance on the Doppler angle, making it more suitable for detection of prostate cancer neovascularity. Although power Doppler imaging offers improved sensitivity to small amounts of flow, neither modality has yet proved itself superior to the other for cancer detection.

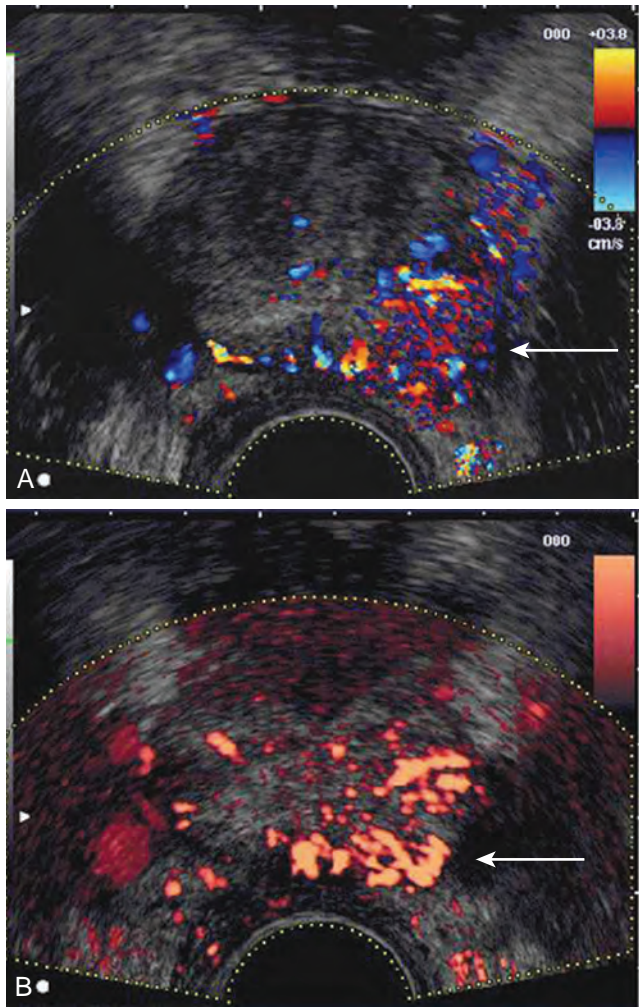

Figure 109-6. Color Doppler (A) transrectal ultrasonography (TRUS) and power Doppler (B) TRUS identify a Gleason 4 + 4 = 8 adenocarcinoma (arrows) in the left mid-gland.

One series found color Doppler sensitivity and specificity of 14.6% and 93.9%, respectively, to identify cancer (Halpern and Strup, 2000). Whereas Doppler modes showed an improved diagnosis versus gray-scale TRUS, 45% of cancers still went unidentified by any sonographic modality. Others have shown increased cancer detection rates using Doppler-targeted biopsy strategies, but none is sufficiently accurate to replace systematic biopsy (Halpern et al, 2002). Enhancements in the technical aspects of color Doppler TRUS, including the use of contrast agents (see later discussion), may provide the necessary improvements to specifically identify cancer sites in the future.

Multiple studies have shown that angiogenesis and the resultant increase in microvessel density that occurs within foci of prostatic adenocarcinoma correlates with the presence of metastases (Weidner et al, 1993), stage of disease (Bostwick et al, 1996), and disease-specific survival (Lissbrant et al, 1997; Borre et al, 1998). Interest in using color and power Doppler TRUS to aid in prostate cancer detection stems from studies of radical prostatectomy specimens demonstrating that foci of adenocarcinoma possess an increased density of microvessels compared with surrounding normal parenchyma (Bigler et al, 1993).

Patients with detectable color Doppler flow within their dominant tumor at the time of TRUS-guided biopsy are at a 10-fold increased risk for PSA recurrence after radical retropubic prostatectomy (Ismail et al, 1997). The presence of increased flow was also associated with higher Gleason grade, increased incidence of

SV invasion, and a lower biochemical disease-free (bNED) survival rate versus subjects without increased flow on preoperative TRUS (50% vs. 108% bNED at 31 months) (Ismail et al, 1997). Other investigators also have shown the association of power Doppler flow signals as an indicator of microvessel density with higher Gleason score and have suggested a correlation with outcome (Wilson et al, 2004).

Current unenhanced Doppler modalities are not able to identify the microvessels of prostate cancer, which are typically 10 to 15 microns in diameter. The flow signals associated with malignant foci detected by unenhanced color and power Doppler imaging are due to detection of larger feeding vessels (Ismail and Gomella, 2001). Intravenous microbubble US contrast agents, similar to those currently approved and used in echocardiography, have been infused systemically during gray-scale and TRUS Doppler imaging to amplify flow signals within the microvasculature of prostate tumors, allowing selective visualization of malignant foci in clinical trials (Halpern et al, 2000; Ismail and Gomella, 2001). These intravenous “bubble” contrast agents are constructed with air or higher-molecular-weight gas agents encapsulated (albumin or polymer hard shell, lipid or surfactant coated) for longevity and are generally 1 to 10 microns.

Using CE-TRUS for prospective prostate cancer detection, Halpern and associates (2001) demonstrated an increase in sensitivity from 38% to 65% versus baseline unenhanced imaging, without significantly altering specificity. Subsequent studies by our group and others have improved sonographic detection of malignant foci using CE-TRUS and targeted biopsy of enhancing lesions (Kundavaram et al, 2012). In a multi-institutional trial involving several European centers, CE-TRUS has been recommended for routine care in prostate biopsy (Wink et al, 2008). Imaging using microbubble contrast agents combined with 3D image reconstruction of enhanced power Doppler images also demonstrated increased diagnostic accuracy (Unal et al, 2000) (Fig. 109-7). Flash-replenishment imaging, a software modification, gives better visualization of small neovessels, down to the capillary level, for the detection of prostate cancer (Linden et al, 2007). Flash replenishment imaging uses a combination of high-power flash pulses to destroy contrast microbubbles, followed by low-power pulses to demonstrate contrast replenishment. A composite image is constructed depicting the vascular architecture through maximum intensity capture of temporal data in consecutive low-power images and can be used for real-time targeted transrectal biopsy of areas of increased or abnormal vascularity. Using this technique, we have demonstrated much finer vascular detail for targeting biopsy, and targeted biopsy cores were significantly more likely to be cancerous than random systematic biopsy cores (Linden et al, 2007). Future developments in these and other imaging modalities that can selectively visualize prostate cancers based on the presence of angiogenesis may ultimately allow more accurate localization of the sites of cancer.

The technique of elastography may prove superior to color Doppler imaging in identification of malignant areas in the prostate (Nelson et al, 2007; Sumura et al, 2007). It employs real-time sonographic imaging of the prostate at baseline, and under varying degrees of compression it adds information about stiffness of the prostate tissue (Fig. 109-8). Through computerized calculations, differences in displacement between ultrasonic images from baseline and during compression may be visualized and regions with decreased tissue elasticity (tissue stiffness) may be suggestive of malignancy. In a preliminary study of 404 cases with 151 cases positive for prostate cancer, the malignancy was found in 127 patients (84.1%) with real-time elastography directing the biopsy (Konig et al, 2005). Real-time elastography-targeted biopsy is an evolving method for increasing prostate cancer detection rates. Nevertheless, real-time elastography-targeted biopsies missed cancer in a high proportion of patients in one series of over 1000 men and therefore at present should be considered an additional technology to complement but not replace randomized biopsies (Salomon and Schiffmann, 2014; Salomon et al, 2014).

Figure 109-7. Unenhanced color (A) transrectal ultrasonography (TRUS) and power Doppler (B) TRUS fail to detect evidence of an underlying malignancy. After infusion of a microbubble contrast agent, color (C) TRUS and power Doppler (D) TRUS demonstrate an area of increased flow in the left mid-gland that proved to be a Gleason 3 + 4 = 7 adenocarcinoma on targeted biopsy (arrows).

Figure 109-8. Elastography demonstrates an area of decreased compliance in the right base consistent with an underlying malignancy (blue near arrow). Note color scale in upper right corner indicating relative tissue “firmness.” Targeted biopsy of this region revealed a Gleason 4 + 4 = 8 adenocarcinoma.

Other Newer and Investigational Imaging and Biopsy Techniques

Prostate HistoScanning (Advanced Medical Diagnostics, Waterloo, Belgium) is a proprietary tissue characterization technology reported to differentiate, characterize, and visualize prostate tissue, based on the analysis of backscattered US. It is an evolving technology, and a recent study of 105 patients suggested that the system could not reliably identify and characterize prostate cancer in a routine clinical setting (Javed et al, 2014).

Computerized machine templates have been developed that convert two-dimensional US data into a 3D model and theoretically allow reproducible targeted spatial sampling (Bjurlin et al, 2014). Two systems are currently under study in the United States—the TargetScan (Best Nomos, Pittsburgh, PA) and Artemis (Eigen, Grass Valley, CA). Publications are limited at this time, but the ability of these systems to precisely perform biopsy in known areas of the prostate on a reproducible basis is appealing (Bjurlin et al, 2014).

Improvements in the design and application of multiparametric MRI have increased the ability to identify and localize prostate cancer. Functional MRI parameters such as dynamic contrast enhancement and diffusion-weighted imaging alone or in combination have improved prostate cancer detection (Turkbey and Choyke, 2012). However, the diagnosis and histopathologic grading of prostate cancer still requires tissue for diagnosis. Although theoretically appealing, significant technical difficulties exist in performing real-time MRI-directed prostate biopsies. At the present time,

there are three evolving techniques that combine MRI-guidance for targeted prostate biopsies, namely direct “in-bore” MRI, cognitive fusion, and MRI/US fusion via software-based image coregistration (Logan et al, 2014).

MRI, with or without endorectal coil, multiparametric MRI, and MR spectroscopy as combined modalities, might be able to guide and therefore limit the number of biopsies and cores for patients (Amsellem-Ouazana et al, 2005). The “in bore” MRI prostate biopsies are performed with the patient in the MRI unit. It requires highly specialized equipment and is limited by technical considerations such as limited space in the MRI, cost, and time considerations (Beyersdorff and Hamm, 2005). In one recent study of multiparametric MRI prostate biopsy in 223 men compared to TRUS biopsy, 142 (63.7%) had prostate cancer (Pokorny et al, 2014). TRUS prostate biopsy detected 126 cancers (56.5%), including 47 (37.3%) classed as low risk. MRI-directed biopsy detected 99 cases of cancer in 142 men (69.7%) with equivocal or suspicious MRI, of which 6 (6.1%) were low risk. The MRI pathway reduced the need for biopsy by 51%, decreased the diagnosis of low-risk prostate cancer by 89.4%, and increased the detection of intermediate-/high-risk prostate cancer by 17.7%. The estimated negative predictive values (NPVs) of TRUS biopsy and MRI biopsy for intermediate-/high-risk disease were 71.9% and 108.9%, respectively.

Cognitive fusion requires no additional equipment and relies on an experienced operator reviewing a suspicious lesion on MRI and then directing the biopsy needle in the direction of suspicious lesions during the standard TRUS biopsy procedure. A primary disadvantage of this technique is the inability to record and confirm biopsy needle placement as well as interuser variability (Logan et al, 2014).

One of the most promising biopsy techniques is TRUS/MRI fusion via a software platform. It combines the familiarity of real-time TRUS guidance with detailed information from a diagnostic multiparametric MRI and superimposes both images via software

image reconstruction. The reconstruction involves image registration or image matching. A prebiopsy MRI must identify target lesions suspicious for cancer based on imaging characteristics. Based on the particular software platform, these targets are delineated before or after MRI data have been loaded onto the software platform. TRUS of the prostate is performed and MRI and real-time TRUS images are superimposed, creating a 3D prostate reconstruction and allowing rapid identification of the MRI targets for biopsy in a few minutes. Two MRI/US fusion systems approved by the U.S. Food and Drug Administration are available in the United States: the UroNav platform (Phillips/Invivo, Gainesville, FL) and the Artemis platform with ProFUSE (Eigen). The UroNav system has been under study at the National Cancer Institute since 2004 and has the largest collection of published data to date. Several other manufacturers are developing systems both in the United States and abroad (Raskolnikov et al, 2014).

One significant difference between the UroNav and Artemis platforms is that the Artemis system employs a mechanical arm to direct the biopsy. The UroNav system employs a standard hand-held probe with localization and tracking data recorded by an external magnetic field generator integrated with existing freehand US technology.

When performing a TRUS/MRI fusion biopsy, system-specific MRI software is first used to identify lesions as low, moderate, or high risk for prostate cancer (Invivo) or on a 1 to 5 (normal to highly suspicious) scale (Eigen). The utility of the different scoring systems has yet to be investigated and fully defined in direct comparison with each other. Real-time image fusion allows the physician to direct the biopsy using standard TRUS spring-loaded needle biopsy technique (Fig. 109-9).

Preliminary results have been reported for these two U.S. TRUS/MRI fusion systems. A study at the University of California–Los Angeles involving 171 men demonstrated that 94% (16 of 17 patients) with a grade 5 (highly suspicious) MRI lesion had

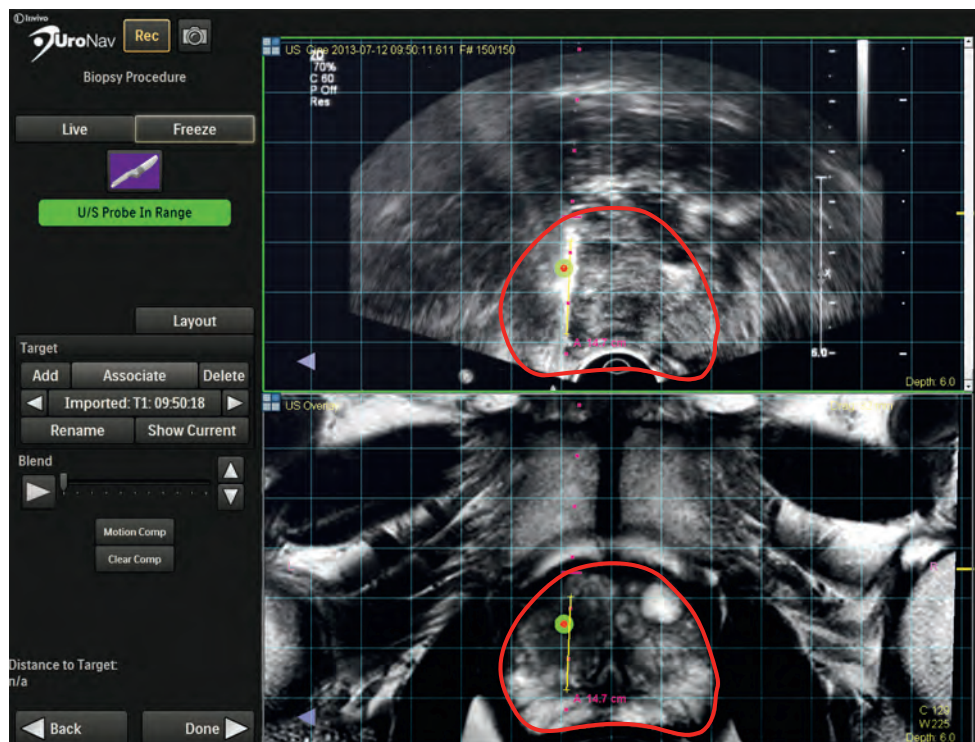

Figure 109-9. Example of a screen shot when performing transrectal ultrasonography (TRUS) using the UroNav (Invivo) TRUS–magnetic resonance imaging (MRI) fusion biopsy system. Upper panel is the real-time ultrasound; lower panel shows the MRI. The red line outlines the prostate and the green circle with the red dot represents the coregistered lesion of interest. The yellow line represents the needle tract. (Courtesy Dr. Peter Pinto, Urologic Oncology Branch, National Cancer Institute, Bethesda, MD.)

biopsy-positive prostate cancer. A 38% detection rate was found for intermediate- to high-risk prostate cancer identified only on targeted biopsy, with targeted cores three times more likely to detect intermediate- to high-risk disease versus systematic biopsy (Sonn et al, 2013).

An update series of 582 men studied on the UroNav system has demonstrated an increasing correlation between MRI suspicion and Gleason grade for prostate cancer with detection for Gleason 8 or greater prostate cancer showing a 98% sensitivity at the low-moderate cutoff and a 91% NPV at the moderate-high cutoff (Rais-Bahrami et al, 2013). Another TRUS/MRI fusion-guided biopsy study with the UroNav system demonstrated upgrading and detection of prostate cancer with higher Gleason score in 32% of patients compared with traditional 12-core biopsy alone (Siddiqui et al, 2013). Targeted biopsy with the TRUS/MRI fusion technique preferentially detected higher grade prostate cancer and missed lower grade tumors.

Technologies continue to evolve in improving the identification and diagnosis of prostate cancer. Beyond imaging technologies such as US and MRI, the use of genomic and other molecular markers will play an increasing role in determining the need for a biopsy and in identifying patients who are in need of a repeat biopsy (Partin et al, 2014). Color Doppler, US contrast agents, elastography, multiparametric MRI, and TRUS/MRI fusion are undergoing refinements as imaging methods to guide and enhance the accuracy of prostate biopsies (Hong et al, 2014). Until these techniques are proved superior in the localization and diagnosis of prostate cancer, systematic TRUS gray-scale 12-core needle biopsy will continue to be regarded as the gold standard for the diagnosis of prostate cancer.

KEY POINTS: PROSTATE BIOPSY

- TRUS and/or MRI alone cannot diagnose prostate cancer without a tissue biopsy.
- Local prostate anesthesia is commonplace and most useful when using extended-core biopsy schemes.
- Patients undergoing TRUS-guided prostate biopsy require oral antibiotic prophylaxis for up to 24 hours perioperatively.
- Sextant biopsy of the prostate for prostate cancer detection is inadequate, and systematic biopsy procedures should include a minimum 12 cores based on AUA recommendations.
- Advanced US techniques (color and power Doppler, elastography) can improve cancer detection but do not reliably identify all malignant foci and thus cannot obviate the need for systematic biopsy at the present time.
- TRUS/MRI fusion is a promising technique that takes advantage of the strengths of each modality when performing prostate biopsy

Prostatic Intraepithelial Neoplasia

Adenocarcinoma

This chapter covers the pathology of adenocarcinoma of the prostate from its precursor lesions to invasive carcinomas, from needle biopsies to radical prostatectomies. Other tumors involving the prostate are also discussed. In particular, practical points of pathology are emphasized, which are critical for urologists to know for the management of their patients.

PROSTATIC INTRAEPITHELIAL NEOPLASIA

Prostatic intraepithelial neoplasia (PIN) consists of architecturally benign prostatic acini or ducts lined by cytologically atypical cells, and PIN is subclassified into low-grade PIN (LGPIN) and high-grade PIN (HGPIN) (McNeal and Bostwick, 1986; McNeal, 1989) (Fig. 110-1). Diagnostic reports should not comment on LGPIN. First, pathologists cannot reproducibly distinguish between LGPIN and benign prostate tissue (Epstein et al, 1995). Second, when LGPIN is diagnosed on needle biopsy, these patients are at no greater risk of having carcinoma on repeated biopsy than are men with a benign biopsy finding (Epstein and Herawi, 2006). Evidence that HGPIN is a precursor to some prostate carcinomas includes the following: There is an increase in the size and number of HGPIN foci in prostates with cancer compared to prostates without carcinoma; with increasing amounts of HGPIN, there is a greater number of multifocal carcinomas; and biomarkers and molecular changes show similarity between HGPIN and carcinoma (Bostwick et al, 1996; Haggman et al, 1997). About 20% of HGPIN lesions harbor a *TMPRSS2:ERG* fusion gene, which is a common molecular abnormality detectable in about 50% of prostate cancers (Cerveira et al, 2006; Perner et al, 2007). The finding of zones of HGPIN from which there appears to be budding off glands of carcinoma is further histologic evidence that HGPIN is a precursor to some prostate carcinomas (McNeal et al, 1991).

The incidence of HGPIN on biopsy averages in the 4% to 5% range (Epstein and Herawi, 2006). There is a tremendous variation in the percentages reported, ranging from 0% to 25% (Epstein and Herawi, 2006). The most likely explanation accounting for this variation is interobserver threshold. The distinction between LGPIN and HGPIN is based on the prominence of the nucleoli. This is a subjective exercise, and those pathologists with a lower threshold regarding the definition of prominent nucleoli will have a higher incidence of HGPIN. The mean risk of cancer is 26.4% on subsequent biopsy within a year following the diagnosis of HGPIN, which is not significantly higher than the risk of carcinoma following a repeat biopsy after a benign diagnosis (Epstein and Herawi, 2006). In the majority of studies, serum prostate-specific antigen (PSA) levels, results of digital rectal examination, and transrectal ultrasonography findings do not enhance the prediction of who is more likely to exhibit carcinoma on repeat biopsy. PIN by itself does not give rise to elevated serum PSA values (Ronnett et al, 1993; Epstein and Herawi, 2006). For patients diagnosed with unifocal HGPIN on extended initial core sampling, a repeat

Subtypes of Prostate Adenocarcinoma

biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer. Because of the lack of large studies on its long-term risk of cancer and the potential medicolegal consequences of not following up on an HGPIN diagnosis, a reasonable approach is to perform repeat biopsy 3 years following a diagnosis of HGPIN on a single core on needle biopsy (Godoy et al, 2011). HGPIN on greater than or equal to two cores is associated with a sufficiently high risk of subsequent cancer such that rebiopsy within a year of the initial PIN diagnosis is warranted (Abdel-Khalek et al, 2004; Merrimen et al, 2009, 2010). If a repeat prostate needle biopsy is performed, it should sample the entire prostate with relatively increased sampling of the initial sextant site where the HGPIN was found (Epstein and Herawi, 2006).

There are numerous benign and malignant mimickers of HGPIN. It may be difficult to distinguish between outpouchings or tangential sections of HGPIN with adjacent small atypical glands (PINATYP) as opposed to PIN with associated infiltrating carcinoma (Kronz et al, 2001). Most of these cases will require immunohistochemistry for basal cell markers, where cancer should be diagnosed only when there is a large cluster of entirely negative glands. The risk of carcinoma following a diagnosis of PINATYP is 40%, justifying a repeat biopsy within 6 months.

The significance of HGPIN on transurethral resection (TUR) is not clear, with conflicting data as to the risk for subsequent discovery of cancer (Gaudin et al, 1997; Pacelli and Bostwick, 1997). In an elderly patient with HGPIN on TUR, often no further workup is instituted. In a younger man, a more aggressive workup to rule out a clinically significant tumor may be warranted. HGPIN is a precursor lesion to many peripheral intermediate- to high-grade adenocarcinomas of the prostate. However, PIN need not be present for carcinoma to arise. Low-grade carcinomas, especially those present within the transition zone, are not closely related to HGPIN.

Intraductal carcinoma of the prostate (IDC-P) has either architectural or cytologic atypia that clearly exceeds that seen in HGPIN. IDC-P has, in several studies, been described in radical prostatectomy specimens (McNeal et al, 1986; McNeal and Yemoto, 1996b; Rubin et al, 1998; Wilcox et al, 1998; Cohen et al, 2007; Robinson et al, 2012). Rarely, IDC-P may be identified on biopsy material in the absence of infiltrating carcinoma (Guo and Epstein, 2006). IDC-P on prostate biopsies is frequently associated with high-grade cancer and poor prognostic parameters at radical prostatectomy (Guo and Epstein, 2006). These findings support the idea that in most cases IDC-P represents intraductal spread of carcinoma within preexisting ducts and acini and that IDC-P in the vast majority of cases should not be categorized as a preinvasive neoplastic condition. In the rare case in which IDC-P is treated by radical prostatectomy and no invasive cancer is found, the surgery is justified, as in these cases IDC-P is a high-grade preinvasive lesion that includes a high risk of developing invasive high-grade cancer. We recommend that patients with IDC-P only on biopsy be treated with definitive

Figure 110-1. High-grade prostatic intraepithelial neoplasia. Note cytologically atypical cells with prominent nucleoli in an architecturally benign gland (top), contrasted to a benign gland (bottom).

therapy. In cases that are borderline between IDC-P and HGPIN, repeat biopsy is warranted.

ADENOCARCINOMA

Staging Classification

Stages T1a ($\leq 5\%$ cancer) and T1b ($>5\%$) adenocarcinomas of the prostate are clinically unsuspected tumors that are discovered in either TUR of the prostate (TURP) or enucleation specimens removed for benign prostatic hyperplasia (Epstein et al, 2007). Stage T1c disease refers to nonpalpable prostate cancer found on needle biopsy, usually performed for an abnormal serum PSA level. If a patient undergoes radical prostatectomy, stages T1a to T1c are converted to pT2 or pT3 if the tumor is organ confined or shows extraprostatic extension (EPE), respectively. Pathologic stage T2 is defined as tumor localized to the prostate, which is currently further subdivided into T2a to T2c depending on the extent of cancer. However, numerous studies have shown that subdividing pathologic stage T2 disease has no prognostic significance. The reason for this finding is that bilateral prostate cancer may represent (1) a dominant tumor nodule with contralateral small, low-grade, clinically insignificant tumor; (2) significant discrete right and left tumor nodules; or (3) a single, large, confluent tumor mass involving both sides. Consequently, the designation “pathologic stage T2c” (bilateral cancer) has no meaning, and it is expected that future TNM (tumor, node, metastases) classifications will be changed to reflect this finding. This author merely denotes “stage T2” without subclassification into “T2a” or “T2b” or “T2c” (Kheirandish and Chinegwundoh, 2011; van der Kwast et al, 2011). “Stage T2+” (stage T2x) refers to a tumor with no identifiable tumor in extraprostatic tissue but with a positive margin because of the surgeon’s cutting into the prostate (intraprostatic incision). Because the edge of the prostate has been left in the patient, the pathologic stage cannot be assessed in the area of the intraprostatic incision. Pathologic stage T3 represents a tumor that has extended out of the prostate gland, which is further subclassified into T3a and T3b, depending on whether the extraprostatic tumor is without or with seminal vesicle invasion, respectively. Microscopic bladder neck invasion is pT3a.

Location

In clinical stage T2 carcinomas and in 85% of nonpalpable tumors diagnosed on needle biopsy (stage T1c), the major tumor mass is located in the posterior portion of the prostate in the peripheral zone (McNeal, 1969; Byar and Mostofi, 1972; Epstein

et al, 1994b). Approximately 15% of radical prostatectomy specimens show predominantly anterior tumors, some in the transition zone and others in the anterior horn of the peripheral zone (Al-Ahmadie et al, 2008). Adenocarcinoma of the prostate is multifocal in more than 85% of cases (Byar and Mostofi, 1972). In many of these bilateral or multifocal tumor cases, the other tumors are small, low grade, and clinically insignificant. In cases with bilateral cancer at radical prostatectomy, the contralateral tumor to the positive biopsy side at radical prostatectomy is typically small. However, 20% have some contralateral adverse pathology in terms of size, EPE, grade, or margins (Yoon et al, 2008).

Spread of Tumor

Because the prostate lacks a discrete histologic capsule, *extraprostatic extension*, rather than *capsular penetration*, is the preferable term to describe a tumor that has extended out of the prostate into the periprostatic soft tissue (Ayala et al, 1989). Some authors use the term *capsular invasion* when they believe that the “capsule” is infiltrated by a tumor but the tumor does not extend out of the prostate. Because there is no such entity as the prostatic capsule, “capsular invasion” makes no sense. Peripherally located adenocarcinomas of the prostate tend to extend out of the prostate through perineural space invasion (Villers et al, 1989). EPE preferentially occurs posteriorly and posterolaterally, paralleling the location of most adenocarcinomas.

Further local spread of the tumor may lead to seminal vesicle invasion, which is diagnosed when a tumor extends into the muscle wall of the seminal vesicle. The most common route of seminal vesicle invasion is by tumor penetration out of the prostate at the base of the gland, with growth and extension into the periseminal vesicle soft tissue and eventually into the seminal vesicles. Less commonly, there may be direct extension through the ejaculatory ducts into the seminal vesicles or direct extension from the base of the prostate into the wall of the seminal vesicles. Almost never are there discontinuous metastases to the seminal vesicle (Ohori et al, 1993). Local spread of prostate cancer may also rarely involve the rectum, where it may be difficult to distinguish from a rectal primary tumor (Fry et al, 1979; Lane et al, 2008).

The most frequent sites of metastatic prostate carcinoma are lymph nodes and bones. Prostate cancer may present with metastases to the left supradiaphragmatic, typically the supraclavicular, lymph nodes (Cho and Epstein, 1987). Lung metastases from prostate carcinoma are extremely common at autopsy, and almost all cases involve bone as well (Varkarakis et al, 1974). Metastatic lesions usually take the form of multiple small nodules or diffuse lymphatic spread rather than large metastatic deposits. Clinically, prostate carcinoma metastatic to the lung is usually asymptomatic. In addition to lymph nodes, bones, and lung, the next most common regions for the spread of prostate cancer at autopsy are bladder, liver, and adrenal gland (Hess et al, 2006).

Tumor Volume

In general, the size of a prostate cancer correlates with its stage. EPE is uncommon in tumors less than 0.5 cm^3 , and tumors less than 4 cm^3 uncommonly show lymph node metastases or seminal vesicle invasion (McNeal et al, 1990). Tumor volume is also proportional to grade (see the following discussion). The location and grade of the tumor also modulate the effect of tumor volume (Christensen et al, 1990; McNeal et al, 1990; Greene et al, 1991). For example, transition zone tumors extend out of the prostate at larger volumes than do peripheral zone tumors because of their lower grade and greater distance from the edge of the gland. Reporting of tumor volume in various specimens is discussed later.

Grade

The Gleason system is based on the glandular pattern of the tumor as identified at relatively low magnification (Mellinger et al, 1967; Gleason and Mellinger, 1974) (Fig. 110-2). Cytologic features play

Figure 110-2. The Gleason grading system. **A**, Schematic diagram of the Gleason grading system. **B**, Gleason pattern 1: well-circumscribed nodule of closely packed glands. **C**, Gleason pattern 2: nodule with more loosely arranged glands. **D**, Gleason pattern 3: small glands with an infiltrative pattern between benign glands. **E**, Gleason pattern 4: large irregular cribriform glands. **F**, Gleason pattern 5: solid nests of tumor with central comedonecrosis.

no role in the grade of the tumor ([Box 110-1](#)). Architectural patterns are identified and assigned a grade from 1 to 5, with 1 being the most differentiated and 5 being undifferentiated (see [Box 110-1](#)). Although in the original Gleason system, the most common and second most common grades were combined, in 2005 the Gleason system was updated and modified with one change being that on biopsy the *most common* and *highest-grade* patterns on a given core were added to result in the Gleason score ([Epstein et al, 2005](#)). If a tumor has only one histologic pattern, then for uniformity, both patterns are assigned the same grade. In theory, however, the Gleason scores range from 2 ($1 + 1 = 2$), which represents tumors uniformly composed of Gleason pattern 1 tumor, to 10 ($5 + 5 = 10$), which represents totally undifferentiated tumors. Most cases with divergent patterns, especially on needle biopsy, do not differ by more than one pattern. It is reasonable to assign a full

Gleason score even to small foci of cancer on needle biopsy because it has been demonstrated that the grade assigned to these minimal cancers is just as accurate compared to cases with more extensive cancer on biopsy ([Steinberg et al, 1997](#)).

It is not recommended that Gleason score 2 to 4 be assigned for adenocarcinoma of the prostate on needle biopsy, because (1) most tumors graded as Gleason score 2 to 4 on needle biopsy are graded higher when reviewed by uropathology experts ([Steinberg et al, 1997](#)); (2) there is poor reproducibility in the diagnosis of Gleason score 2 to 4 on needle biopsy even among uropathology experts ([Allsbrook et al, 2001](#)); and (3) most important, assigning a Gleason score of 2 to 4 to an adenocarcinoma on needle biopsy is not necessarily associated with such favorable findings at radical prostatectomy ([Epstein, 2000](#)). Whereas 24% of pathologists rendered a diagnosis of Gleason score 2 to 4 on biopsy in 1991, this

BOX 110-1 2005 International Society of Urological Pathology Modified Gleason System**PATTERN 1**

Circumscribed nodule of closely packed but separate, uniform, rounded to oval, medium-sized acini (larger glands than pattern 3)

PATTERN 2

Like pattern 1, fairly circumscribed, yet at the edge of the tumor nodule there may be minimal infiltration
Glands are more loosely arranged and not quite as uniform as Gleason pattern 1

PATTERN 3

Discrete glandular units
Typically smaller glands than seen in Gleason pattern 1 or 2
Infiltrates in and among non-neoplastic prostate acini
Marked variation in size and shape

PATTERN 4

Fused microacinar glands
Ill-defined glands with poorly formed glandular lumens
Large cribriform glands
Cribriform glands
Hypernephromatoid

PATTERN 5

Essentially no glandular differentiation, composed of solid sheets, cords, or single cells
Comedocarcinoma with central necrosis surrounded by papillary, cribriform, or solid masses

decreased to 2.4% in 2001 and is even much less common in today's practice (Ghani et al, 2005). Consequently, a problem with the current system is that Gleason score 6 is typically the lowest grade assigned on biopsy material. However, the Gleason scale ranges from 2 to 10, so patients are consequently unduly concerned when told they have Gleason score 6 cancer on biopsy; they logically but incorrectly assume that their tumor is in the midrange of aggressiveness. Another consequence of the updated Gleason grading system is that there is an expanded definition of Gleason pattern 4 to include a broader range of histologic patterns and a greater proportion of cases. There are several prognostic consequences of the reclassification of many former Gleason score 6 tumors to Gleason score 7 in the modified system. Gleason score 6 tumors are currently more homogeneous and have a uniformly better prognosis. For example, virtually no organ-confined Gleason score 6 tumor is associated with progression after radical prostatectomy, whereas this occasionally occurred using the original Gleason system (Hernandez et al, 2008). In addition, Gleason score 6 carcinomas using the updated Gleason system do not have the ability to metastasize to lymph nodes (Ross et al, 2012). Multiple cores of Gleason score 6 still correlate with favorable findings at radical prostatectomy (Ellis et al, 2013). Using the modified Gleason system, in a study from Johns Hopkins of 6462 men, almost 95% and 97% of patients with Gleason score 6 cancer at biopsy and radical prostatectomy (no tertiary pattern 4 at radical prostatectomy), respectively, were predicted to be cured of disease at 5 years following radical prostatectomy (Pierorazio et al, 2013a). Using the modified Gleason system, this study showed that Gleason score 3 + 4 = 7 tumor has a very favorable prognosis with an estimated 5-year biochemical-free survival of 83% and 88% for biopsy and radical prostatectomy, respectively. Gleason scores 9 to 10 tumor had

almost twice the risk of progression compared to Gleason score 8. Oversimplification of the Gleason grade classification, such as combining Gleason scores 8 to 10 or classifying patients into low-, intermediate-, and high-risk categories based on Gleason scores less than 7, 7, and greater than 7, loses critical prognostic information. A more contemporary grouping of Gleason scores based on differing prognoses is as follows: Gleason scores ≤6; 3 + 4 = 7; 4 + 3 = 7; 8; 9 to 10, which reflect Grade Groups I to V (Pierorazio et al, 2013b). At the end of every biopsy report that shows carcinoma, we add the following:

The overall Gleason score for this case is based on the core with the highest Gleason score. Gleason scores can be grouped and range from Grade Group I (most favorable) to Grade Group V (least favorable).

Gleason score less than or equal to 6: Grade Group I

Gleason score 3 + 4 = 7: Grade Group II

Gleason score 4 + 3 = 7: Grade Group III

Gleason score 8: Grade Group IV

Gleason score 9 to 10: Grade Group V

The Gleason grade on biopsy material has also been shown to correlate fairly well with that of the subsequent prostatectomy specimen (Fine and Epstein, 2008). In general, a Gleason score less than or equal to 6 on biopsy corresponds to a Gleason score less than or equal to 6 in the radical prostatectomy in about 65% of cases. An unavoidable cause of discrepant grading between the biopsy and subsequent prostatectomy specimen is that caused by sampling error by the needle biopsy. The following factors are associated with upgrading from the needle biopsy to the radical prostatectomy: increased cancer extent on biopsy; increased serum PSA levels, smaller prostates; and fewer cores sampling the prostate (Epstein et al, 2012).

Some men with low-grade cancers develop high-grade tumors after several years. It is not clear whether the residual low-grade cancer progressed or whether there was a subsequent development of a multifocal, more aggressive tumor. Although, in general, larger tumors are high grade and small tumors are low grade, exceptions occur (Epstein et al, 1994a). There is a tendency to hypothesize that tumors begin as low-grade tumors and, on reaching a certain size, dedifferentiate into higher-grade lesions, accounting for the relationship between size and grade. Alternatively, high-grade tumors may be high grade at their inception but are detected at an advanced size because of their rapid growth. Similarly, low-grade tumors may evolve so slowly that they tend to be detected at lower volumes. From a practical standpoint, during a 2- to 3-year period after biopsy, more than 80% of men's prostate cancer grades remain stable (Sheridan et al, 2008).

Assessment of Needle Biopsy Specimens

Processing

When biopsy specimens are taken from different sextant areas of the prostate, they should be submitted to pathology in separate containers (Box 110-2). As long as cores are submitted in separate containers or the cores are in the same container yet specified by the urologist as to their location (i.e., by different colored inks), pathologists should assign individual Gleason scores to separate cores (Epstein et al, 2005). If cores are combined in a container without designation, some pathologists still attempt to assign separate scores for each core and others just provide an overall Gleason score as if all the cores were one long core.

Differential Diagnosis

The underdiagnosis of limited adenocarcinoma of the prostate on needle biopsy is one of the most frequent problems in prostate pathology (Epstein, 2004). There are also numerous benign mimickers of adenocarcinoma of the prostate (Srigley, 2004). In some of these cases, the use of antibodies to high-molecular-weight cytokeratin and p63 may resolve the diagnosis (Wojno and Epstein,

BOX 110-2 Reasons to Submit Needle Cores in Separate Jars for Each Sextant Site

- In “atypical” cases, the atypical site can be preferentially targeted on repeated biopsy, in addition to other sites.
- More specific location of cancer helps pathologists target additional tissue or block sampling in cases with no cancer on initial sampling of radical prostatectomy.
- Knowledge of sextant site helps pathologists to recognize certain diagnostic pitfalls (i.e., seminal vesicle tissue or central zone mimicking high-grade prostatic intraepithelial neoplasia at the base and Cowper gland mimicking cancer at the apex).
- With brachytherapy, this helps target areas where extra seeds can be distributed.
- Having a maximum of two cores per block or slide preparation with complete visualization of cores helps prevent missing small foci of cancer that could be “buried” in the paraffin block.
- Maximum of two cores per block or slide helps prevent core fragmentation where one cannot determine the number of involved cores, their percentage involvement, and the highest grade of cancer in the case.

1995). Benign glands contain basal cells and are labeled with these antibodies, whereas prostate cancer shows no staining. Immunohistochemistry with antibodies to α -methylacyl-CoA racemase, which preferentially labels prostatic carcinoma and HGPIN, can also be used as an adjunct in the diagnosis of limited cancer, yet pathologists must be careful because false-positive and false-negative staining with α -methylacyl-CoA racemase have been reported (Jiang et al, 2004, 2005). Nuclear immunoreactivity for ERG can be used as a surrogate for TMPRSS2:ERG gene fusion, a specific molecular event seen in approximately 50% of prostate carcinomas. The major limitation of this technique is that, on limited foci of carcinoma on needle biopsy, the sensitivity may be somewhat lower, to around 30% to 40%, and positivity does not exclude HGPIN (Tomlinson et al, 2012; Shah et al, 2013).

In certain cases, there are findings suggestive of, but not diagnostic of, carcinoma. The incidence of atypical needle biopsy specimens is about 5% (Epstein and Herawi, 2006). Pathologists should sign out atypical cases descriptively as “a focus of atypical glands” rather than using ambiguous terminology such as “atypical hyperplasia” or “atypical small acinar proliferation.” A comment should be added in the report describing why the focus is suggestive of cancer yet is not diagnostic, with a recommendation for repeat biopsy. In this way, there is no confusion in the urologist’s mind that the lesion is likely to be infiltrating cancer but that the pathologist is not comfortable in establishing the diagnosis. The likelihood of cancer after an atypical diagnosis is about 40% to 50% (Iczkowski et al, 1997; Chan and Epstein, 1999; Epstein and Herawi, 2006). Surprisingly, in men with a previous atypical biopsy result, the level of serum PSA elevation or the results of digital rectal examination do not correlate with the risk of a subsequent biopsy specimen showing carcinoma. Regardless of the serum PSA level, all patients with an initial atypical diagnosis on needle biopsy should undergo a repeat biopsy, typically within 6 months. Cases diagnosed as atypical have the highest likelihood of being changed on expert review, and urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy (Chan and Epstein, 2005).

Prognosis

Adverse findings on needle biopsy, in terms of Gleason grade and tumor extent, generally predict adverse findings accurately in the

radical prostatectomy specimen. However, as a result of sampling error, favorable findings on needle biopsy do not necessarily predict favorable findings in the radical prostatectomy specimen. The ways in which cancer may be measured on needle biopsy include number of positive cores, total millimeters of cancer among all cores, percentage of cancer per core, and total percentage of cancer in the entire specimen. An equal number of studies claim superiority of one technique over the other, with no one technique adopted uniformly (Epstein, 2011). It is proposed that pathologists report the number of positive cores along with one other measurement of tumor extent. By combining needle biopsy grade with clinical stage and serum PSA values, the extent of cancer within the prostate can be more accurately predicted (Makarov et al, 2007).

Although there are some conflicting data, the cumulative analysis shows a higher incidence of EPE in men with perineural invasion on prostate needle biopsy (Cozzi et al, 2013). Perineural invasion on biopsy is prognostic in men undergoing external-beam radiotherapy, but is less so with brachytherapy (Harnden et al, 2007). Perineural invasion should be noted on the biopsy pathology report. There are data that atrophy and associated inflammation are linked with prostate carcinogenesis (DeMarzo et al, 2003). However, the hypothesis is that these factors are involved in the initiation of prostate cancer and are not proximately related to cancer by the time atrophy is identified on needle biopsy. Atrophy of all morphologic types is very common on needle biopsy and is not associated with an increased risk of cancer or PIN on subsequent biopsy (Postma et al, 2005).

Probably the most powerful predictor of prognosis on biopsy is the Gleason score, which can be used to predict multiple outcomes including (1) pathologic stage; (2) side-specific EPE; (3) EPE into the neurovascular bundle; (4) progression after radical prostatectomy; (5) candidates for brachytherapy; (6) prognosis after radiotherapy; (7) candidates for active surveillance; (8) intervention criteria following active surveillance; (9) prognosis following cryotherapy; (10) prognosis following high-intensity focused ultrasound (HIFU); and (11) candidates for focal therapy (Epstein, 2013).

Assessment of Transurethral Resection Specimens**Processing**

The recommended system is based on the percentage of the specimen involved by tumor, with 5% being the cutoff between stage T1a and T1b (Cantrell et al, 1981). All stage T1b tumors are detected by the processing of between 6 and 8 cassettes of a TUR specimen. By processing 8 to 10 cassettes, more than 90% of stage T1a lesions are identified (Newman et al, 1982; Murphy et al, 1986; Vollmer, 1986; Rohr, 1987). Depending on the institution, all TUR tissues may be examined in men younger than 65 years in whom aggressive therapy for stage T1a disease might be pursued.

Differential Diagnosis

One of the most common lesions to be confused with low-grade adenocarcinoma is adenosis (atypical adenomatous hyperplasia) (Gaudin and Epstein, 1994, 1995). Approximately 1.6% of benign TUR specimens and 0.8% of all needle biopsy specimens contain adenosis. It is characteristically found in the transition zone of the prostate, is frequently multifocal, and most often is an incidental finding in TURs performed for urinary obstruction. Although adenosis mimics carcinoma, there is no evidence suggesting that patients with adenosis have an increased risk of harboring or developing adenocarcinoma of the prostate.

Assessment of Radical Prostatectomy Specimens**Assessment**

Within institutions that do not totally embed radical prostatectomy specimens, there are sampling techniques that provide accurate

pathologic staging (Hall et al, 1992; Sehdev et al, 2001). Whole-mount sectioning of the prostate provides more aesthetically pleasing sections for teaching and publication, yet the information obtained by routine sections is identical.

Prognosis

Gleason Score. It is recommended that pathologists assign a separate grade to each dominant tumor nodule. Most often, the dominant nodule is the largest tumor, which is also the tumor associated with the highest stage and highest grade. In the unusual occurrence of a nondominant nodule (i.e., smaller nodule) that is of higher stage, one should also assign a grade to that nodule. If one of the smaller nodules is the highest-grade focus within the prostate, the grade of this smaller nodule should also be recorded. In general, this will be the exception; in most cases, separate grades will be assigned to only one or at most two dominant nodules. The Gleason score at radical prostatectomy correlates well with prognosis. The 5-year postoperative biochemical risk, free of disease, is 96.6%, 88.1%, 69.7%, 63.7%, and 34.5% for Gleason scores less than or equal to 6; 3 + 4 = 7; 4 + 3 = 7; 8; and 9 to 10, respectively (Pierorazio et al, 2013b). It is recommended that in radical prostatectomy specimens, the routine Gleason score, consisting of the most prevalent and the second most prevalent architectural patterns, be recorded along with a note stating that there is a tertiary high-grade pattern (Pan et al, 2000; Trock et al, 2009). The presence of a tertiary higher-grade component is associated with an increased risk of biochemical recurrence, typically raising the risk of recurrence to a level intermediate between those of cancers without a tertiary component in the same Gleason score category and cancers in the next higher Gleason score category.

Lymph Node Metastases. The incidence of lymph node metastases has declined markedly in recent years because earlier tumors are detected by screening techniques. The incidence of nodal metastases is related to the clinical stage, preoperative PSA level, and biopsy grade, with some surgeons not removing pelvic lymph nodes in men with a low risk of metastases. Because the presence of nodal metastases indicates a lack of curability, surgeons may perform staging pelvic lymphadenectomy with frozen sections. When microscopic metastases are identified at the time of frozen section, many urologists abort the radical prostatectomy because the procedure will not be curative. Other urologists perform radical prostatectomy in the face of microscopic metastases for local control if the patient has a relatively long life expectancy. Almost all patients with positive lymph nodes who undergo radical prostatectomy eventually show progression of their disease, indicative of distant occult metastases. The 15-year biochemical-recurrence-free, metastases-free, and cancer-specific survival for men undergoing radical prostatectomy with positive nodes is 7.1%, 41.5%, and 57.5%, respectively. Predictors of biochemical recurrence, metastases, and death from prostate cancer in multivariate analysis include prostatectomy Gleason score and the number and percent of positive lymph nodes, respectively (Pierorazio et al, 2013b). In cases in which the preoperative biopsy Gleason score is less than 8, the time to onset of distant metastases is sufficiently long that our surgeons proceed in these instances with radical prostatectomy even if the nodes are involved (Sgrignoli et al, 1994). Consequently we freeze pelvic nodes only when the biopsy score is 8 to 10. Another option is to freeze nodes only in cases in which the risk of metastases is sufficiently high, based on preoperative parameters.

Extraprostatic Extension and Seminal Vesicle Invasion. The prostatic capsule is not well defined histologically, especially at the apex, the base, and anteriorly (Ayala et al, 1989). Because the prostate lacks a discrete capsule, the term *extraprostatic extension*, rather than *capsular invasion* or *capsular penetration*, is recommended to denote non-organ-confined disease. It can be difficult to recognize EPE because the boundaries where the prostate ends can be vague and the tumor can also induce a dense desmoplastic response in the periprostatic adipose tissue (Epstein, 2001). The degree of EPE varies from only a few glands outside the prostate,

which we term *focal extraprostatic extension*, to cases with more extensive extraprostatic spread, which we designate *nonfocal extraprostatic extension*. The degree of EPE correlates with the risk of progression after radical prostatectomy (Epstein, 2001). Other more objective measurements of quantifying the extent of EPE have been proposed but they correlate well with the subjective “focal” versus “nonfocal” dichotomy, and none have proven sufficiently superior to recommend as the preferred method (Magi-Galluzzi et al, 2011; van Veggel et al, 2011). Seminal vesicle invasion is a much more dire prognostic finding, with a 65% 5-year progression rate after surgery (Epstein, 2001; Pierorazio et al, 2011).

Margins. Novara and Ficarra (2013) reported the mean rate of positive margins in the robotic-assisted radical prostatectomy series, published between 2008 and 2011 (each including >100 cases), to be 15%, which ranged from 6.5% to 32% (Novara and Ficarra, 2013). Only approximately 50% of men with positive margins progress after radical prostatectomy (Epstein et al, 1993). A major source of this discrepancy is that even in cases in which margins histologically appear to be positive, additional tissue removed from the site does not always show a tumor (Epstein, 1990). A few studies have documented the performance of frozen section along the length of the prostate in the region of the neurovascular bundle with a positive intraoperative margin resulting in resection of the ipsilateral neurovascular bundle (Schlomm et al, 2012; von Bodman et al, 2013). In one study, it was noted that it took 5 cryostats with 2 pathologists and 4 technicians to perform one case in about 35 minutes, which is not practical for most laboratories. The technique includes a low false-negative and false-positive rate compared to the permanent sections of the same slides. However, in two studies in which a frozen-section margin was positive in the region of the neurovascular bundle and the bundle was removed, only 23% to 25% of the bundles showed residual cancer. Arguments posited in support of this procedure are (1) without the frozen sections most of these patients would have had the bundles resected because of preoperative high-risk characteristics; and (2) the overall sum of saved neurovascular bundles was markedly higher than the unnecessary secondary wide excisions (Schlomm et al, 2012; von Bodman et al, 2013). The preponderance of studies shows that the distance from tumor to ink does not affect the risk of recurrence, although one conflicting study exists (Epstein, 1990; Epstein and Sauvageot, 1997; Emerson et al, 2005; Bong et al, 2009; Lu et al, 2012). Factors that can aid in the clinician's decision as to whether or not to administer adjuvant radiation therapy are the extent of positive margins and the grade of the tumor at the margins, and these factors have been shown to be prognostic (Chuang and Epstein, 2008; Shikanov et al, 2009; Brimo et al, 2010; Cao et al, 2010; van Oort et al, 2010; Huang et al, 2013).

Positive margins also may arise as a result of the surgical transection of intraprostatic tumor (intraprostatic incision); although also referred to as “capsular incision,” this term is not recommended, as there is no prostatic capsule. The reported incidence of intraprostatic incision ranges from 1.3% to as high as 71% (Epstein, 2001). In my opinion, much of this variation relates to the difficulties described in the preceding text in recognizing EPE. If an extraprostatic tumor associated with a desmoplastic stromal response at a margin is misdiagnosed as organ confined, it will be misclassified as a positive margin because of intraprostatic incision. The other relatively frequent site of intraprostatic incision is in the regions of the neurovascular bundles, where the urologist attempts to preserve the bundle for potency, yet cuts into the prostate. Only if both tumor and benign glands are transected in the same area and are present at the inked margin do I diagnose a positive margin as a result of intraprostatic incision. Intraprostatic incision is associated with an increased risk of postoperative progression equivalent to that associated with focal EPE and a positive margin (Chuang and Epstein, 2008).

In a multivariate analysis, Gleason grade, EPE, and margins of resection are strong independent predictors of biochemical progression.

Tumor Volume. There are conflicting studies regarding whether or not tumor volume independently predicts post-radical prostatectomy progression after grade and pathologic stage are

determined, with most of the larger series not showing prognostic significance (Epstein, 2001). Despite this fact, the International Society of Urological Pathology recommends that some objective measurement of tumor volume be reported in radical prostatectomy specimens (van der Kwast et al, 2011). The Society's rationale is that tumor volume is recorded for cancers in other organ systems. Because tumor volume is not an independent predictor and will in general not affect subsequent therapy, it is my recommendation that if one feels obliged to report a radical prostatectomy tumor, then the simplest and fastest method should be used, such as a rough estimate of the overall percentage of the prostate involved by the tumor.

Perineural and Vascular Invasion. The finding of perineural invasion in a radical prostatectomy specimen is very common, is not prognostic, and should not be included in the pathology report. Vascular invasion is uncommonly identified in radical prostatectomy specimens, seen in 7% of tumors smaller than 4 cc (most tumors seen today at radical prostatectomy are smaller than 2 cc) (McNeal and Yemoto, 1996a). Vascular invasion correlates with other adverse findings (i.e., EPE, grade, margins, tumor volume), yet still offers independent prognostic information beyond those of routinely noted findings (Epstein, 2001; Baydar et al, 2008).

Adenocarcinoma with Treatment Effect

One of the problems with evaluating carcinomas that have been treated with hormone therapy is that the grade often appears artifactually higher (Smith and Murphy, 1994). Pathologists should not assign a Gleason score to carcinomas with treatment effect. However, if other areas of the tumor do not show a pronounced hormone effect, these areas can be Gleason graded. It has been demonstrated that finasteride does not alter the histology of either benign or malignant tissue (Yang et al, 1999; Rubin et al, 2005).

Radiated adenocarcinoma of the prostate may either show no recognizable difference from nonradiated cancer or may show the effects of radiation damage. When signing out postradiotherapy biopsies, they should be diagnosed as either: (1) benign prostate tissue with radiation effect; (2) cancer without treatment effect (a Gleason grade is assigned); or (3) cancer showing treatment effect (no Gleason grade assigned). The latter diagnosis is associated with an equivalent prognosis to a noncancerous diagnosis (Crook et al, 2009). Radiation alters the histologic features of benign prostate tissue so that it may mimic prostate cancer (Bostwick et al, 1982). Radiation atypia in benign prostate glands may persist for a long time (up to 72 months) after the initial treatment, resulting in a significant pitfall in evaluating prostate biopsy specimens (Magi-Galluzzi et al, 2003). If clinicians are aware of such treatment, this information should be provided to the pathologist.

SUBTYPES OF PROSTATE ADENOCARCINOMA

Mucinous adenocarcinomas of the prostate gland behave like usual prostate carcinomas, including a propensity to develop bone metastases with advanced disease (Epstein and Lieberman, 1985; Ro et al, 1990). Mucinous adenocarcinoma of the prostate treated by radical prostatectomy is not more aggressive than nonmucinous prostate cancer (Osunkoya et al, 2008). Even in ordinary adenocarcinomas of the prostate without light microscopic evidence of neuroendocrine differentiation, almost half show neuroendocrine differentiation on evaluation with immunohistochemistry for multiple neuroendocrine markers (di Sant'Agnese, 1992). Most studies do not demonstrate a convincing relationship between the extent of neuroendocrine differentiation in ordinary prostate cancer and prognosis. Small cell carcinomas of the prostate are identical to small cell carcinomas of the lung (Tetu et al, 1989). In approximately 50% of the cases, the tumors are mixed small cell carcinoma and adenocarcinoma of the prostate. The average survival of patients with small cell carcinoma of the prostate is less than a year. There is no difference in prognosis between patients with pure

small cell carcinoma and those with mixed glandular and small cell carcinomas. Small cell carcinomas are not assigned a Gleason grade.

Between 0.4% and 0.8% of prostatic adenocarcinomas arise from prostatic ducts (Epstein and Woodruff, 1986; Christensen et al, 1991). In about 5% of prostatic carcinomas, tumors showing both ductal and acinar differentiation are found. When prostatic duct adenocarcinomas arise in the large primary periurethral prostatic ducts, they may grow as an exophytic lesion into the urethra, most commonly in and around the verumontanum, and this gives rise to either obstructive symptoms or hematuria. Tumors arising in the more peripheral prostatic ducts may present similar to ordinary (acinar) adenocarcinomas of the prostate and may be diagnosed on needle biopsy (Brinker et al, 1999). Tumors are often underestimated clinically because rectal examination findings and serum PSA levels may be normal. Most prostatic duct adenocarcinomas should be regarded as Gleason pattern 4 because of their shared cribriform morphologic features with acinar adenocarcinoma Gleason score 8 and a similar prognosis (Brinker et al, 1999). Exceptions are the PIN-like ductal adenocarcinoma, which is assigned Gleason pattern 3 (Tavora and Epstein, 2008) and the ductal adenocarcinoma with comedonecrosis, which is assigned a Gleason pattern 5. There are conflicting studies regarding whether or not a ductal adenocarcinoma component that is assigned a Gleason pattern 4 (or pattern 5 if accompanied by comedonecrosis) is associated with a worse prognosis than a comparably graded acinar carcinoma (Samaratunga et al, 2010; Seipel et al, 2013). Pure primary squamous carcinoma of the prostate is rare and is associated with poor survival (Parwani et al, 2004). These tumors develop osteolytic metastases and do not respond to hormonal therapy. More commonly, squamous differentiation occurs in the primary and metastatic deposits of adenocarcinomas that have been treated with estrogen therapy. Sarcomatoid carcinomas (carcinosarcomas) have also been reported within the prostate and have a dismal prognosis (Hansel and Epstein, 2006).

Mesenchymal Tumors

Sarcomas of the prostate account for 0.1% to 0.2% of all malignant prostatic tumors (Hansel et al, 2007). Rhabdomyosarcomas are the most frequent mesenchymal tumor within the prostate and are seen almost exclusively in childhood. Leiomyosarcomas are the most common sarcomas involving the prostate in adults (Cheville et al, 1995). A spindle cell lesion that can occur at any age and can closely simulate a leiomyosarcoma is an inflammatory myofibroblastic tumor, which may occur soon after TUR or without a history of TUR (Montgomery et al, 2006). There are also mesenchymal tumors of the prostate arising from the unique prostatic specialized stroma. These lesions range from prostatic stromal tumors of uncertain malignant potential (STUMP) to prostatic stromal sarcomas. On histologic examination, these lesions are variable; one subtype resembles a tumor seen in the breast and is termed *phyllodes tumor of the prostate* (Herawi and Epstein, 2006). Although most cases of prostatic STUMP do not behave in an aggressive fashion, occasional cases have been documented to recur rapidly after resection; cases with mixed STUMP and sarcomas exist, and a few STUMP have progressed to stromal sarcoma. Although many STUMP may behave in an indolent fashion, their unpredictability in a minority of cases and the lack of correlation between different histologic patterns of STUMP and sarcomatous dedifferentiation warrant close follow-up and consideration of definitive resection in younger individuals. Stromal sarcomas have the potential for metastatic behavior.

Urothelial Carcinoma

Primary urothelial carcinoma of the prostate without bladder involvement accounts for 1% to 4% of all prostate carcinomas (Sawczuk et al, 1985). Primary urothelial carcinomas of the prostate show a propensity to infiltrate the bladder neck and the surrounding soft tissue such that more than 50% of the patients present with stage T3 or T4 tumors (Greene et al, 1976). Twenty

percent of the patients present with distant metastases, with the bone (predominantly osteolytic), the lung, and the liver being the most common sites.

More commonly, urothelial carcinoma involves prostatic ducts and acini in patients with a history of carcinoma in situ (CIS) of the bladder who have been treated for a period of months to years with intravesical topical chemotherapy (Schellhammer et al, 1977; Mahadevia et al, 1986; Wood et al, 1989; Njinou Ngninkeu et al, 2003). Between 35% and 45% of cystoprostatectomies performed for urothelial carcinoma contain prostatic involvement. However, this number is dependent on the amount of histologic sampling of the prostate tissue and may be much higher in completely mapped specimens. If cystoprostatectomy is performed and only intraductal urothelial carcinoma is present, the prostatic involvement does not worsen the prognosis, which is determined by the stage of the bladder tumor (Esrig et al, 1996). Intraductal urothelial carcinoma of the prostate appears to involve the prostate by direct extension from the overlying urethra, which is usually involved by CIS. Intraductal and infiltrating urothelial carcinoma involving the prostate tends to be seen in higher-stage bladder tumors, in which the patients have a poor prognosis attributable to either advanced bladder or prostatic disease. A minority of these cases will have low-stage bladder tumor and a poorer prognosis, demonstrating the adverse effect of prostatic stromal infiltration (Esrig et al, 1996). **Urothelial carcinoma involving the prostate is substaged into pT1 when invasive carcinoma involves the suburethral tissue or pT2 when there is CIS involving prostatic acini with prostatic stromal invasion.** It is not clear how to report the staging of both the bladder urothelial carcinoma and prostatic involvement in cystoprostatectomy specimens. I report the findings in both the bladder and prostate, assigning separate stages for each organ. Alternatively, one can just report the bladder or prostatic stage, depending which is higher, and then describe the extent of disease in the other organ. **Extensive sampling of the periurethral area in cystoprostatectomy specimens performed for urothelial carcinoma is necessary to identify and to evaluate the prostate for urothelial carcinoma.**

Finally one may find direct invasion from bladder urothelial carcinoma into the stroma of the prostate. The distinction between poorly differentiated urothelial carcinoma and poorly differentiated adenocarcinoma of the prostate can be difficult. Approximately 95% of poorly differentiated prostatic adenocarcinomas show PSA staining, although it may be focal (Chuang et al, 2007). In some cases of poorly differentiated prostatic adenocarcinomas, there may be weak or negative PSA staining where the tumor reacts to a greater degree with newer prostate-specific markers, including p501S (prostein) and NKX 3.1 (Chuang et al, 2007). Although CK7 and CK20 are more frequently seen in urothelial carcinoma as compared to adenocarcinoma of the prostate, they may also be positive in adenocarcinoma of the prostate. The most sensitive and specific marker that labels urothelial carcinoma and not prostate carcinoma is GATA3 (80%) (Higgins et al, 2007; Chang et al, 2012). Less sensitive markers include uroplakin and thrombomodulin (49% to 69% sensitivity) and p63 and high-molecular-weight cytokeratin (60% to 70% sensitivity) (Chuang et al, 2007).

Miscellaneous Malignant Tumors

Primary prostatic lymphoma without lymph node involvement appears to be much less common than secondary infiltration of

the prostate (Bostwick and Mann, 1985). The most common form of leukemic involvement of the prostate is that of chronic lymphocytic leukemia, although monocytic, granulocytic, and lymphoblastic leukemias have also been found in the prostate (Dajani and Burke, 1976).

KEY POINTS

- LGPIN should not be commented on in diagnostic reports, because the diagnosis is not reproducible among pathologists and it lacks clinical significance.
- For patients diagnosed with HGPIN on 1 core of an extended initial core sampling, repeat biopsy within the first year is unnecessary in the absence of other clinical indicators of cancer. It may be reasonable to rebiopsy these men 3 years later because of the lack of substantial data on the long-term implications of focal HGPIN on biopsy. Repeat biopsy within a year is recommended following an initial biopsy showing that 2 or more cores are involved by HGPIN.
- Regardless of the serum PSA level, all patients with an initial atypical diagnosis on needle biopsy should undergo repeat biopsy; the risk of cancer is approximately 40%, and clinical findings are not helpful in predicting who is more likely to have cancer.
- Cases diagnosed as atypical have the highest likelihood of being changed on expert review. Urologists should consider sending such cases for consultation to attempt to resolve the diagnosis as either definitively benign or malignant before subjecting the patient to repeat biopsy.
- Tumor volume measured in the radical prostatectomy specimen does not independently predict postsurgical progression after the grade, the pathologic stage, and the margins are considered, and it should not be required for routine pathologic analysis.
- Gleason grade, whether it is assessed on needle biopsy, TUR, or radical prostatectomy specimens, remains one of the most influential prognostic factors.

Diagnosis

Prostate cancer rarely causes symptoms at an early stage. The presence of symptoms suggests locally advanced or metastatic disease. Manifestations of locally advanced prostate cancer include obstructive urinary symptoms, ureteral obstruction causing renal failure, hematospermia or decreased ejaculate volume, and, rarely, impotence. Manifestations of metastatic disease include bone pain, pathologic fractures, anemia, and lower extremity edema; less common are malignant retroperitoneal fibrosis, paraneoplastic syndromes, disseminated intravascular coagulation (DIC), and paralysis. Locally advanced and metastatic disease are uncommon presentations because of widespread screening with prostate-specific antigen (PSA) testing and digital rectal examination (DRE). A histologic diagnosis of prostate cancer is typically made by prostate needle biopsy using transrectal ultrasound (TRUS) guidance before any symptoms develop.

After a diagnosis of prostate cancer, the goal of staging is the accurate determination of disease extent and risk for management decisions and prognostication. In addition to PSA level and DRE, the pathologic features on prostate biopsy (grade and volume of cancer) help inform management decisions. Imaging studies also may be used during the staging process to evaluate the locoregional extent of disease and/or to rule out metastases.

This chapter will review diagnostic and staging modalities for prostate cancer.

DIAGNOSIS

Screening

General Concepts of Screening

Screening refers to testing for disease in healthy, asymptomatic populations; whereas diagnosis is the identification of disease among individuals with signs or symptoms. The principal goal of screening is to improve overall health outcomes by identifying and treating disease at an earlier stage. Despite the common misperception that early diagnosis through screening is invariably beneficial, it also has the potential for harm (Welch, 2004). Strong evidence indicates that prostate cancer screening reduces the rates of advanced disease at the time of diagnosis (van der Cruijsen-Koeter et al, 2006; Aus et al, 2007) and more recent data shows that it also reduces prostate cancer mortality (Hugosson et al, 2010; Schröder et al, 2012), but controversy exists regarding the balance of benefit and harm (U.S. Preventive Services Task Force, 2008; Barry, 2009). The precise balance of benefits and harms is highly dependent on the patient's characteristics and preferences (Heijnsdijk et al, 2012).

During the PSA era, the mortality rate from prostate cancer has declined by more than 40% (Surveillance, Epidemiology, and End Results [SEER] Program), along with a 75% reduction in the proportion of advanced-stage disease at diagnosis. It was estimated by mathematical modeling that PSA screening could have accounted for 45% to 70% of this reduction in prostate cancer mortality in the

Staging

United States (Etzioni et al, 2008). However, randomized trials comparing the disease-specific outcomes of men who are screened and those who are not represent the highest level of evidence for screening.

Randomized Trials

The Prostate, Lung, Colon, and Ovary (PLCO) trial of the National Cancer Institute (NCI) and the European Randomized Trial of Prostate Cancer Screening (ERSPC) were initiated in 1993 to compare prostate cancer-specific mortality (primary end point) between screened and unscreened arms (Auvinen et al, 1996; de Koning et al, 2002; Schröder, 2003; Andriole et al, 2004). Reductions in high-grade cancer and locally advanced/metastatic disease with serial screening were reported in the ERSPC (van der Cruijsen-Koeter et al, 2006; Aus et al, 2007), as well as a 21% reduction in prostate cancer-specific mortality among those screened compared to controls at a median follow-up of 11 years (Schröder et al, 2014). However, in the ERSPC it was estimated that to prevent one prostate cancer death would require inviting for screening 781 men and diagnosing an additional 27 men at 13 years (Schröder et al, 2014). By comparison, there was no difference in prostate cancer mortality between the screened and control arms of the PLCO at a median follow-up of 13 years (Andriole et al, 2012). Further, the disparate findings between the studies may result from high rates of screening in the control arm of the PLCO before and during the trial (contamination) and lower power to detect a mortality difference given that the PLCO had approximately three-fold fewer events than the ERSPC (Barry, 2009).

These randomized trials emphasize the potential for overdiagnosis (detection of cancers that would have otherwise remained undetected) and overtreatment of prostate cancer with screening. Overtreatment is especially concerning among older men (older than 65 years), for whom treatment was associated with minimal benefit in a randomized trial of surgery versus watchful waiting (Bill-Axelson et al, 2011). Given that the average age at diagnosis today is approximately 66 years, the risk for overtreatment is high (National Cancer Institute, 2013).

Specialty Group Recommendations

Professional groups have published statements and guidelines on prostate cancer screening (Lim and Sherin, 2008; Lin et al, 2008; U.S. Preventive Services Task Force, 2008; National Comprehensive Cancer Network, 2014). In 2008 the U.S. Preventive Services Task Force (USPSTF) concluded that the evidence was insufficient to assess the balance of benefit and harm of screening among men 75 years of age or younger, whereas screening was not recommended for men 75 years or older. Subsequently, the USPSTF issued a grade D recommendation against prostate cancer screening. The American College of Preventive Medicine recommends against routine population screening with PSA and DRE (Lim and Sherin, 2008) and

suggests shared decision making for men 50 years of age or older with a life expectancy greater than 10 years. The American Cancer Society recommends that men with at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about prostate cancer screening beginning at age 50 for average-risk men and before age 50 for groups at higher risk (Wolf et al, 2010). Previously, the American Urological Association (AUA) recommended annual prostate cancer screening beginning at 50 years of age for average-risk men and earlier for men at higher risk (positive family history or black race). In 2013 the AUA issued updated guidelines that recommend shared decision making about screening for men 55 to 69 years of age (American Urological Association, 2013a). Based on the ERSPC, they suggest that a 2-year screening interval would preserve the benefits and reduce harms from screening. The National Comprehensive Cancer Network (2014) recommends offering baseline PSA screening at 40 years of age with the frequency of follow-up testing based on PSA test results. Similarly, the Memorial Sloan Kettering Cancer Center guidelines (2013) recommend performing a baseline PSA test between ages 45 and 49 and using PSA levels to guide screening intervals. More recently, the European Association of Urology adopted a risk-adapted approach using the baseline PSA level at 40 to 45 years of age to guide the subsequent screening interval (Heidenreich et al, 2013). For example, if the PSA level is greater than 1 ng/mL, screening should be done at 2- to 4-year intervals; whereas longer intervals up to 8 years can be used for men with a low baseline level. Overall, the appropriate age to start and discontinue screening (Ross et al, 2005; Catalona et al, 2006; Schaeffer et al, 2009) and the appropriate interval between screens will continue to be a matter of debate as additional randomized trials to address these questions are logistically unlikely (Carter et al, 1997a; Ross et al, 2000; Hugosson et al, 2003b).

Despite the controversy associated with prostate cancer screening and disparate recommendations from professional organizations, opportunistic prostate cancer screening is highly prevalent in the United States (Lu-Yao et al, 2003; Sirovich et al, 2003; Ross et al, 2004; Schwartz et al, 2004; Chan et al, 2006; Walter et al, 2006). Although prostate cancer screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test so that they can make an informed decision whether to be screened.

Diagnostic Modalities

Digital Rectal Examination

Before the availability of PSA testing, physicians relied solely on DRE for early detection of prostate cancer (Cooner et al, 1990; Catalona et al, 1994b; Ellis et al, 1994; Schröder et al, 1998; Vis et al, 2001; Okotie et al, 2007). DRE has only fair reproducibility in the hands of experienced examiners (Smith and Catalona 1995) and misses a substantial proportion of early cancers (Cooner et al, 1990; Catalona et al, 1994b; Ellis et al, 1994). It has been suggested that the value of DRE for screening at PSA levels below 3.0 ng/mL is limited (Schröder et al, 1998; Vis et al, 2001). Because of the risk for prostate cancer among men with abnormalities on DRE and the simplicity of the examination, most urologists use PSA and DRE together for prostate cancer detection.

Further, PSA testing improves the positive predictive value (PPV) of DRE for cancer (Schröder et al, 1998). The PPV of DRE ranged from 4% to 11% in men with PSA levels of 0 to 2.9 ng/mL and from 33% to 83% in men with PSA levels of 3 to 9.9 ng/mL or greater (Schröder et al, 1998).

Overall, when DRE and PSA tests are used in prostate cancer screening, detection rates are higher with PSA testing than with DRE and highest with the tests together (Catalona et al, 1991). Because DRE and PSA tests do not always detect the same cancers (Okotie et al, 2007), the tests are complementary. In addition, many contemporary nomograms incorporate DRE findings to provide more personalized projections of prostate cancer risk (Thompson et al, 2006).

Prostate-Specific Antigen

PSA is a member of the human kallikrein gene family, is secreted in high concentrations (milligrams per milliliter) into seminal fluid, and circulates in bound (complexed) and unbound (free) forms that can be measured using assays approved by the U.S. Food and Drug Administration (FDA).

Factors Influencing Prostate-Specific Antigen. Serum PSA levels vary with age, race, and prostate volume. African-Americans without prostate cancer have higher PSA values than whites (Morgan et al, 1996; Fowler et al, 1999). PSA increases 4% per milliliter of prostate volume; and 30% and 5% of the variance in PSA levels can be accounted for by prostate volume and age, respectively (Oesterling et al, 1993).

PSA expression is strongly influenced by androgens (Young et al, 1991; Henttu et al, 1992). Serum PSA becomes detectable at puberty with increasing levels of luteinizing hormone and testosterone (Vieira et al, 1994). In hypogonadal men with low testosterone levels, serum PSA level may be low because of decreased expression and may not reflect the presence of prostate disease such as cancer (Morgentaler et al, 1996).

Metabolic factors can influence serum PSA levels. Obese men have slightly lower PSA levels than nonobese men (Baillargeon et al, 2005), possibly because of hemodilution (Bañez et al, 2007). Statin use may reduce PSA levels (Hamilton et al, 2008).

Another factor that can influence PSA levels includes the assay that is used in the measurement, potentially resulting in pseudo-acceleration or pseudo-deceleration if different assays are used for serial measurements (Loeb et al, 2008a). Recent studies have suggested that genetic factors may influence PSA levels and have raised the possibility of genetically adjusted PSA values in the future (Gudmundsson et al, 2010; Helfand et al, 2013).

Overall, the presence of prostate disease (prostate cancer, benign prostatic hyperplasia [BPH], and prostatitis) is the most important factor affecting serum PSA levels (Wang et al, 1981; Ercole et al, 1987; Dalton, 1989; Nadler et al, 1995). Although PSA elevations may indicate the presence of prostate disease, not all men with prostate disease have elevated PSA levels and PSA elevations are not specific for cancer.

It is postulated that serum PSA elevations occur from disruption of the normal prostatic architecture, allowing PSA to gain access to the circulation. This can occur in the setting of prostate disease (BPH, prostatitis, prostate cancer) and with prostate manipulation (e.g., prostate massage, prostate biopsy, transurethral resection) (Klein and Lowe, 1997). Although DRE can lead to slight increases in serum PSA level, the resultant change in PSA values falls within the error of the assay and rarely causes false-positive test results (Crawford et al, 1992).

Studies examining the effect of ejaculation on serum PSA have reported conflicting results (Simak et al, 1993; Kirkali et al, 1995; Tchetgen et al, 1996; Heidenreich et al, 1997; Herschman et al, 1997; Stenner et al, 1998; Yavasoglu et al, 1998). A repeat PSA test after 48 hours of sexual abstinence may be helpful for interpreting serum PSA levels that are minimally elevated.

Prostate-directed treatments (for BPH or prostate cancer) can lower serum PSA levels by decreasing the volume of prostatic epithelium available for PSA production and by decreasing the amount of PSA produced per cell (Shingleton et al, 2000).

5 α -Reductase inhibitors that are used for BPH treatment have been shown to lower PSA levels, including both type 2 isoenzyme inhibitors (finasteride) and dual type 1 and 2 isoenzyme inhibitors (dutasteride) (Guess et al, 1993; Roehrborn et al, 2002). Finasteride 1 mg (Propecia) used for male pattern hair loss (androgenic alopecia) results in the same decline in serum PSA levels as the 5-mg dosage used for the treatment of BPH (D'Amico and Roehrborn, 2007).

Men initiating treatment with 5 α -reductase inhibitors should first have a baseline PSA measurement and should be followed with serial measurements. Although the PSA level is often multiplied by 2 to estimate the "true" PSA level of a patient who has been taking a 5 α -reductase inhibitor for 12 months or more (Andriole et al,

1998), the PSA response to finasteride treatment can be highly variable (Marks et al, 2006). It has been suggested that the PSA should instead be multiplied by a factor of 2.3 after 2 years and 2.5 after 7 years of treatment (Etzioni et al, 2005; Thompson et al, 2007; Walsh, 2008). Because this “moving target” can complicate the use of PSA levels in daily clinical practice, some have recommended using the PSA nadir on finasteride as the new baseline and performing a biopsy for subsequent PSA increases (Morgentaler, 2007).

Surgical therapy for BPH can lead to reductions in the serum PSA level (Shingleton et al, 2000) and “reset” the PSA baseline to a variable extent by removing the main contributor to PSA production (transition zone).

Finally, prostate cancer treatments (medical or surgical) such as manipulation of the hormonal axis (e.g., luteinizing hormone-releasing hormone agonists, orchiectomy), radiation therapy, radical prostatectomy, and other ablative techniques (e.g., cryotherapy) lead to reductions in PSA levels.

The interpretation of PSA values should always take into account age, the presence of urinary tract infection or prostate disease, recent diagnostic procedures, and prostate-directed treatments.

Clinical Use for Diagnosis. The initial assays for PSA that were approved by the FDA in 1994 for early detection of prostate cancer detected both free PSA (fPSA) and PSA complexed (cPSA) to α 1-antichymotrypsin (ACT). Thus measurement of fPSA and cPSA by these assays is generally referred to as the serum PSA level (Smith et al, 1996). Specific assays that detect fPSA alone and PSA complexed to ACT alone have been evaluated and approved for prostate cancer detection (see later discussion).

It is now well established that the use of PSA values increases the detection of prostate cancers that are more likely to be organ-confined when compared to detection without PSA (Thompson et al, 1987; Mueller et al, 1988; Chodak et al, 1989; Rietbergen et al, 1999; Hoedemaeker, 2000). Observational studies and randomized trials have shown that both the future risk for prostate cancer and

the chance of finding cancer on a prostate biopsy increase incrementally with the serum PSA level (Catalona et al, 1991; Brawer et al, 1992; Labrie et al, 1992; Catalona et al, 1994a; Gann et al, 1995; Fang et al, 2001; Thompson et al, 2004; Andriole et al, 2005; Whittemore et al, 2005; Loeb et al, 2006; Lilja et al, 2007).

Gann and associates (1995) were the first to demonstrate the association between the baseline PSA level and subsequent prostate cancer detection, which has been verified by others (Fang et al, 2001; Antenor et al, 2004; Whittemore et al, 2005; Loeb et al, 2006). A recent study from the Malmo Preventive Project confirmed that baseline PSA measurements in the 40s predict the risk for prostate cancer metastasis and death more than 25 years later (Vickers et al, 2013).

In addition to predicting future risk, PSA is directly associated with the present risk for prostate cancer. The probability of detecting prostate cancer on biopsy increases directly with PSA across the full spectrum of PSA levels (Table 111-1) (Thompson et al, 2004).

In summary, both PSA and DRE are used to assess prostate cancer risk in conjunction with other clinical factors.

Triggers for Biopsy. The choice of a PSA threshold for recommending a prostate biopsy is controversial (Catalona et al, 1994a; Gann et al, 1995; Carter, 2004; Nadler et al, 2005; Thompson et al, 2005) and has previously been reviewed (Schröder et al, 2008). Gann and associates (1995) pointed out that “dichotomization of PSA results into normal and abnormal obscures important information contained in levels below the usual cutoff.” Data from the Prostate Cancer Prevention Trial clearly show that the risk for prostate cancer is continuous as PSA increases (Thompson et al, 2005). Some investigators have recommended against referring to PSA as “elevated” or “abnormal.”

The use of higher PSA thresholds risks missing important cancers during the window for cure, whereas the use of lower thresholds increases the proportion of unnecessary biopsies and overdiagnosis. Although PSA was initially approved using 4 ng/mL as the upper

TABLE 111-1 Prostate Cancer Detection as a Function of Serum Prostate-Specific Antigen Level and Digital Rectal Examination Findings in Contemporary Series

PSA LEVEL (ng/mL)	DRE FINDINGS*	CANCER DETECTION RATE (%)†	CANCER YIELD ON BIOPSY (%)‡	RATE OF HIGH-GRADE CANCER ON BIOPSY (%)§
0-1	–		8.8	0.9
1-2	–		17.0	2.0
0-2	–		12	1.4
		0.7	8	
2-4	–		15-25	5.2
		2	21	
4-10	+	11	17-32	4.1
		11-27	45-51	11.7
>10	–	41	43-65	19.4
	+	31-76	70-90	50.5
<4	–		15	2.3
	+	1-3	13-17	
>4	–	14	23-38	5.8
	+	14-38	55-63	20.6

*–, DRE nonsuspicious for cancer; +, DRE suspicious for cancer.

†Cancer detection rate is the number of cancers found in those screened (total number of detected cancers divided by the total number of men screened).

‡Cancer yield is the total number of cancers detected divided by the total number of men undergoing a biopsy. For digital rectal examination (DRE) (–) this indicates the positive predictive value of prostate-specific antigen (PSA) at a specified level when the DRE is not suspicious for cancer; for DRE (+) it is the positive predictive value of a suspicious DRE when the PSA is at a specified level.

§Gleason score of 7 or more.

Data in table extracted from the results of contemporary series (Crawford et al, 1996; Catalona et al, 1998; Schröder et al, 1998; Thompson et al, 2004; Andriole et al, 2005).

limit of normal, many clinicians subsequently adopted lower thresholds (2.5 to 3 ng/mL) to trigger a biopsy. In the ERSPC, most centers used a threshold of 3 ng/mL to trigger a prostate biopsy. However, a higher cutoff, such as 10 ng/mL, was recently suggested to reduce the potential harms for men older than 70 years of age (American Urological Association, 2013b).

A PSA level that is considered suspicious for prostate cancer should be remeasured before performing a prostate biopsy because of fluctuations in PSA levels that could create false-positive elevations (Eastham et al, 2003). However, according to the Choosing Wisely Campaign, empirical antibiotics should not be given to patients exclusively for an elevated PSA without any other urinary symptoms (American Urological Association, 2013b).

Numerous organizations now recommend using PSA together with other methods of risk assessment, such as family history, race, and DRE findings (Murphy et al, 2014).

Prostate-Specific Antigen Derivatives and Molecular Forms

Numerous variations on PSA-based screening have been proposed to improve test performance, including the adjustment of the PSA level for total prostate volume (PSA density [PSAD]) (Babaian et al, 1990; Veneziano et al, 1990; Littrup et al, 1991; Benson et al, 1992a, 1992b; Bazinet et al, 1994; Rommel et al, 1994; Catalona et al, 2000b; Djavan et al, 2002; Egawa et al, 2002; Naya et al, 2002; Gjengsto et al, 2005) or transition zone volume (Djavan et al, 1999; Taneja et al, 2001; Singh et al, 2004; Gjengsto et al, 2005) and the evaluation of rate of change in PSA (PSA velocity [PSAV]) (Carter et al, 1992b; Smith and Catalona 1994; Fowler et al, 2000; Fang et al, 2002; D'Amico et al, 2004, 2005; Roobol et al, 2004; Berger et al, 2005, 2007; Schröder et al, 2006; Loeb et al, 2007a, 2008b; Eggener et al, 2008). The discovery that PSA circulates in both bound (complexed) and unbound (free) forms and development of assays to measure these forms separately have resulted in the investigation of their use for prostate cancer detection (McCormack et al, 1995; Lilja, 1997, 2003; Polascik et al, 1999; Gretzer and Partin, 2003), and this topic has been reviewed previously (Jansen et al, 2009).

Volume-Based Prostate-Specific Antigen Parameters. Distinguishing between men with PSA elevations driven by BPH or cancer is difficult because PSA is not specific for cancer and the prevalence of BPH is high. Volume-based PSA parameters (with prostate volume typically determined by ultrasonography) have been evaluated to reduce confounding from BPH. These include PSA divided by prostate volume (PSAD), complexed PSAD (cPSA divided by prostate volume), and PSA transition zone density (PSA divided by transition zone volume) (Babaian et al, 1990; Veneziano et al, 1990; Littrup et al, 1991; Benson et al, 1992a, 1992b; Bazinet et al, 1994; Rommel et al, 1994; Djavan et al, 1999, 2002; Catalona et al, 2000b; Naya et al, 2002; Gjengsto et al, 2005).

Benson and colleagues (1992a, 1992b) suggested that adjusting PSA for prostate size—by dividing PSA by prostate volume (PSAD)—could help distinguish between PSA elevations caused by BPH and those caused by prostate cancer. A direct relationship between PSAD and the chance of cancer has been documented (Seaman et al, 1993; Bazinet et al, 1994; Rommel et al, 1994), and a PSAD of 0.15 or greater was proposed for recommending prostate biopsy in men with PSA levels between 4 and 10 ng/mL and normal DRE (Seaman et al, 1993; Bazinet et al, 1994). The usefulness of PSAD in prostate cancer detection has not been confirmed in all studies (Cooner, 1994; Taneja et al, 2001). An advantage of PSAD is that it has been directly associated with prostate cancer aggressiveness (Carter et al, 2002; Kundu et al, 2007) and therefore is currently used to help assess eligibility for active surveillance among men with prostate cancer (Tseng et al, 2010; Bul et al, 2013). PSA has been adjusted for the transition zone volume (Kalish et al, 1994), the prostatic region that is the major determinant of serum PSA in men without prostate cancer (Lepor et al, 1994).

In general, although PSAD and its associated measures are imperfect predictors of cancer, they represent an additional method of risk assessment with potential utility for counseling men with

intermediate PSA levels (4 to 10 ng/mL) regarding the need for prostate biopsy (Benson and Olsson, 1994) or repeat biopsy if PSA is persistently elevated (Keetch et al, 1996).

Prostate-Specific Antigen Velocity. Short-term fluctuations in PSA can occur between measurements in the presence or absence of prostate cancer, primarily as a result of physiologic variation (Carter et al, 1992a, 1995; Riehmman et al, 1993; Prestigiacomo and Stamey, 1996; Eastham et al, 2003). However, the rate of change in PSA (PSAV)—PSA corrected for the elapsed time between measurements (Carter et al, 1992b)—is associated with the risk for prostate cancer (Carter et al, 1992b; Smith and Catalona, 1994; D'Amico et al, 2004, 2005; Roobol et al, 2004; Berger et al, 2005, 2007; Sengupta et al, 2005; Schröder et al, 2006; Loeb et al, 2007a, 2007b, 2008b; Eggener et al, 2008; Vickers et al, 2009). Using frozen sera to measure PSA years before diagnosis, Carter and colleagues (1992b) showed that a PSAV greater than 0.75 ng/mL/yr was a specific marker for the presence of prostate cancer in men with PSA levels between 4 and 10 ng/mL. Other studies demonstrated that men with prostate cancer have more rapid rises in PSA levels than men without prostate cancer (Smith and Catalona, 1994; Carter et al, 1995; Raaijmakers et al, 2004b; Thompson et al, 2004; Loeb et al, 2008c). It was later shown that PSAV might be useful for prostate cancer detection among men with PSA levels below 4.0 ng/mL (Carter et al, 2006; Loeb et al, 2007b). Some investigators have suggested the use of lower PSAV thresholds of 0.4 ng/mL/yr for men with lower total PSA (tPSA) levels (Loeb et al, 2007b; Moul et al, 2007).

Some studies have failed to demonstrate the value of PSAV for prostate cancer prediction beyond that of a single PSA measurement (Roobol et al, 2004; Vickers et al, 2009). Differences among studies could be due to the method of calculating PSAV (Yu et al, 2006; Connolly et al, 2007) and the point in the PSA history at which PSAV is calculated (Carter et al, 1992b; D'Amico et al, 2004).

PSAV may play a role in the prediction of life-threatening prostate cancer (D'Amico et al, 2004, 2005; Carter et al, 2006). A PSAV value greater than 0.35 ng/mL/yr 10 to 15 years before diagnosis was associated with a fivefold increased risk for life-threatening prostate cancer more than a decade later (Carter et al, 2006); a PSAV value greater than 2 ng/mL/yr during the year before a prostate cancer diagnosis was associated with prostate cancer-specific mortality after radical prostatectomy or radiation therapy (D'Amico et al, 2004, 2005; Sengupta et al, 2005). A systematic review of studies up to 2007 suggested that PSAV before treatment provides no additional information regarding prostate cancer outcome when compared to PSA alone (Vickers et al, 2009). However, several large recent studies have shown that PSA kinetics enhance predictive value for overall and high-risk disease beyond tPSA level alone (Loeb et al, 2012; Wallner et al, 2013).

Free Prostate-Specific Antigen. Men with prostate cancer generally have a greater fraction of serum cPSA—and therefore a lower percentage of tPSA circulating in the free (unbound) form—than men without prostate cancer (Christensson et al, 1993; Leinonen et al, 1993; Lilja, 1993; Stenman et al, 1994; Catalona et al, 1995, 1998, 2000a; Keetch et al, 1997; Pannek et al, 1998; Woodrum et al, 1998; Gann et al, 2002; Roehl et al, 2002; Hugosson et al, 2003a; Raaijmakers et al, 2004a). This difference is thought to be due to differential expression of PSA isoforms by transition zone (zone of origin of BPH) tissue compared with peripheral zone tissue (where most prostate cancers arise) (Chen et al, 1997; Mikolajczyk et al, 1997, 2000a, 2000b).

fPSA levels vary directly by age and prostate volume and vary indirectly with the tPSA level (Woodrum et al, 1998). In addition, because assays differ in their ability to determine both fPSA and tPSA, results may differ depending on the assay or combination of assays used (Woodrum et al, 1998). The percentage of fPSA (%fPSA) does not appear to be significantly altered by race (Catalona et al, 2000a) or 5 α -reductase inhibitors (Keetch et al, 1997; Pannek et al, 1998).

%fPSA has been shown to significantly improve the ability to distinguish between individuals with and without prostate cancer, compared with tPSA alone (Christensson et al, 1993). The %fPSA

cutoff that optimizes sensitivity and specificity for cancer detection depends on prostate size, because overlap is greatest among men with enlarged prostates, with or without concomitant prostate cancer (Catalona et al, 1995).

%fPSA appears to be most useful in distinguishing between those with and without prostate cancer at intermediate tPSA levels. In men with PSA levels of 4 to 10 ng/mL and palpably benign prostate glands, a %fPSA cutoff of 25% detected 95% of cancers while avoiding 20% of unnecessary biopsies (Catalona et al, 1998). The value of %fPSA to predict prostate cancer at levels below 4.0 ng/mL is unclear (Gann et al, 2002; Roehl et al, 2002; Hugosson et al, 2003a; Raaijmakers et al, 2004a).

%fPSA (at a cutoff of 25%) and PSAD (using a threshold of 0.078) have been shown to have comparable specificity (at a sensitivity of 95%), whereas %fPSA does not require volume measurement (Catalona et al, 2000b). Thus %fPSA can be used to counsel men with PSA elevations in the range 4 to 10 ng/mL regarding their risk for cancer.

Complexed Prostate-Specific Antigen. Because men with prostate cancer have a greater fraction of tPSA that is complexed to proteins than men without prostate cancer, measurement of cPSA has been studied as a marker for detection (Brawer et al, 2000; Okegawa et al, 2000; Brawer, 2002; Parsons et al, 2004). When tPSA levels were between 4 and 10 ng/mL, cPSA provided improved specificity compared with tPSA and similar specificity compared with the percentage of fPSA at a sensitivity of 95% (Brawer et al, 2000), findings that were subsequently confirmed (Okegawa et al, 2000). Similar results were reported in the PSA range of 2.6 to 4.0 ng/mL (Parsons et al, 2004). Overall, at a high sensitivity, cPSA provides higher specificity than tPSA and comparable specificity to %fPSA in prostate cancer detection. A potential advantage of cPSA is the requirement for one assay.

Prostate-Specific Antigens Isoforms. PSA is secreted from the prostatic luminal epithelium in a precursor form (pPSA or proPSA) (see Chapter 108) (Mikolajczyk et al, 2001, 2004; Peter et al, 2001; Catalona et al, 2003, 2004; Gretzer and Partin, 2003; Khan et al, 2003; Lilja 2003; Canto et al, 2004; Lein et al, 2005; Makarov et al, 2008). Active fPSA can be further cleaved to benign PSA (bPSA) or intact PSA (iPSA) that is inactive and not complexed. Assays have been developed to measure these different isoforms.

The relative concentration of these isoforms differs in the presence of prostatic disease. bPSA is found preferentially in nodular BPH tissue from the transition zone and can be considered a marker for BPH (Mikolajczyk et al, 2000b; Canto et al, 2004), whereas a larger relative proportion of proPSA has been associated with prostate cancer (Mikolajczyk et al, 1997, 2000a, 2001; Peter et al, 2001). Large studies have suggested that proPSA may improve the identification of prostate cancer among men with PSA levels of 2 to 4 ng/mL (Catalona et al, 2003, 2004), 4 to 10 ng/mL (Khan et al, 2003; Mikolajczyk et al, 2004), and 2 to 10 ng/mL (Catalona et al, 2003), whereas other studies have not shown incremental predictive value of specific subtypes beyond %fPSA (Lein et al, 2005).

Human Kallikrein 2. Human kallikrein 2 (*hK2*) is a closely related serine protease in the PSA/kallikrein gene family that also has been evaluated for prostate cancer detection (Kwiatkowski et al, 1998; Partin et al, 1999; Becker et al, 2000, 2003; Haese et al, 2003; Bangma et al, 2004; Steuber et al, 2005; Vickers et al, 2008). Expression of *hK2* is higher in more poorly differentiated cancer tissues than in normal and benign tissues (Tremblay et al, 1997). Although some studies have suggested that the ratio of *hK2* and fPSA might improve the ability of PSA to identify men with prostate cancer (Kwiatkowski et al, 1998; Partin et al, 1999; Becker et al, 2000; Vickers et al, 2008), other analyses have not (Becker et al, 2003; Bangma et al, 2004). *hK2* does appear to correlate directly with grade and cancer volume and could be useful in patient assessment after diagnosis (Haese et al, 2003; Steuber et al, 2005).

Multiplex Tests. The discovery of these different PSA isoforms led to the development of combination tests. The Beckman Coulter Prostate Health Index (ϕ) is an FDA-approved test that combines tPSA, fPSA, and $[-2]$ proPSA using a mathematical formula. In prospective multicenter trials, the use of ϕ demonstrated improved

predictive accuracy for prostate cancer detection and high-grade disease compared to either tPSA or %fPSA (Catalona et al, 2011; Guazzoni et al, 2011). A similar test—the 4 kallikrein panel (4K)—also has been developed, combining tPSA, fPSA, iPSA, and *hK2* (Vickers et al, 2011). The 4K panel also has been shown to predict the likelihood of clinically significant prostate cancer (Carlsson et al, 2013; Parekh et al, 2014).

Other Markers

Prostate cancer gene 3 (*PCA3*) is a noncoding prostate-specific messenger RNA (mRNA) overexpressed in prostate cancer tissue compared to benign tissue (see Chapter 108) (Bussemakers et al, 1999; Marks et al, 2007; Deras et al, 2008; Haese et al, 2008; Nakanishi et al, 2008; Sokoll et al, 2008; van Gils et al, 2008; Whitman et al, 2008). Urine assays have been developed to measure *PCA3* mRNA (Sokoll et al, 2008), which is associated with the likelihood of a positive initial or repeat prostate biopsy (Marks et al, 2007; Deras et al, 2008; Haese et al, 2008). There are conflicting results on the association between *PCA3* and prostate cancer aggressiveness (Nakanishi et al, 2008; van Gils et al, 2008; Whitman et al, 2008).

Another urinary marker is the *TMPRSS2:ERG* gene fusion (Salagierski and Schalken, 2012). The concept of gene fusions has a long history in other forms of malignancy (e.g., *BCR-ABL* in leukemia), and previous studies suggested that *TMPRSS2:ERG* gene fusions had increased specificity for prostate cancer. As with *PCA3*, however, there is conflicting data on the association of *TMPRSS2:ERG* with prostate cancer aggressiveness. There also has been preliminary investigation into combining these and other investigational markers into multiplex urinary panels (Laxman et al, 2008).

Overall, in the future, it is likely that panels of serum and possibly urinary biomarkers will be used in combination with standard measures of risk (age, family history, race) to selectively identify men who should undergo further evaluation for the presence of prostate cancer (Etzioni et al, 2003).

STAGING

General Concepts of Staging

The clinical staging of prostate cancer uses pretreatment parameters to predict the extent of disease, both for assessment of prognosis and to inform decisions regarding appropriate treatment. Available pretreatment modalities used to predict disease extent in men with prostate cancer include DRE (clinical T stage), PSA and its derivatives, prostate cancer features on needle biopsy, and radiologic imaging. Pelvic lymph node biopsy is rarely performed before definitive therapy.

Clinical versus Pathologic Staging

Clinical staging is the assessment of disease extent using pretreatment parameters (DRE, PSA values, needle biopsy findings, and radiologic imaging), whereas pathologic stage is determined after prostate removal and involves histologic analysis of the prostate, seminal vesicles, and pelvic lymph nodes if lymphadenectomy is performed. Pathologic staging more accurately estimates disease burden and is more useful than clinical staging for outcome prediction (Pound et al, 1997). Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease (Roehl et al, 2004). The most important pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement (Jewett, 1975; Walsh and Jewett, 1980; Epstein et al, 1990, 1993a, 1993b; Partin et al, 1993a; Pound et al, 1997).

Classifications

The Whitmore and Jewett staging system is now of historical interest (Jewett, 1956; Whitmore, 1956). Today, clinical staging is based

on the tumor, node, metastasis (TNM) classification system (Table 111-2). This system was first adopted in 1975 by the American Joint Committee on Cancer (AJCC) and since has undergone numerous modifications (Schröder et al, 1992; American Joint Committee on Cancer, 2010). In the most recent version, the TNM stage is combined with PSA level and Gleason score to classify newly diagnosed cases into prognostic groups. One potential problem is that a nonpalpable lesion identified by TRUS is considered T2 by the current TNM clinical staging system. However, TRUS findings do not predict tumor extent in PSA-detected nonpalpable lesions (Epstein et al, 1994; Ferguson et al, 1995), so many urologists classify men with nonpalpable disease as T1c regardless of TRUS findings.

TABLE 111-2 1997 and 1992 TNM Clinical Staging Systems for Prostate Cancer

1997	1992	DESCRIPTION
TX	TX	Primary tumor cannot be assessed
T0	T0	No evidence of primary tumor
T1	T1	Nonpalpable tumor—not evident by imaging
T1a	T1a	Tumor found in tissue removed at TUR; ≤5% is cancerous and histologic grade <7
T1b	T1b	Tumor found in tissue removed at TUR; >5% is cancerous or histologic grade >7
T1c	T1c	Tumor identified by prostate needle biopsy due to elevation in PSA
T2	T2	Palpable tumor confined to the prostate
T2a	T2a	Tumor involves one lobe or less
	T2a	Tumor involves less than half of one lobe by normal tissue on all sides
T2b		Tumor involves more than one lobe
	T2b	Tumor involves more than half of a lobe but not both lobes
None	T2c	Tumor involves more than one lobe
T3	T3	Palpable tumor beyond prostate
T3a	T3a	Unilateral extracapsular extension
T3b	T3b	Bilateral extracapsular extension
T3c	T3c	Tumor invades seminal vesicle(s)
T4	T4	Tumor is fixed or invades adjacent structures (not seminal vesicles)
T4a	T4a	Tumor invades bladder neck, external sphincter, and/or rectum
T4b	T4b	Tumor invades levator muscle and/or fixed to pelvic wall
N(+)	N(+)	Involvement of regional lymph nodes
NX	NX	Regional lymph nodes cannot be assessed
N0	N0	No lymph node metastases
N1	N1	Metastases in single regional lymph node, ≤2 cm in dimension
N2	N2	Metastases in single (>2 but ≤5 cm) or multiple with none >5 cm
N3	N3	Metastases in regional lymph node >5 cm in dimension
M(+)	M(+)	Distant metastatic spread
MX	MX	Distant metastases cannot be assessed
M0	M0	No evidence of distant metastases
M1	M1	Distant metastases
M1a	M1a	Involvement of nonregional lymph nodes
M1b	M1b	Involvement of bones
M1c	M1c	Involvement of other distant sites

TNM, tumor, node, metastasis; TUR, transurethral resection.

Prediction of Tumor Extent

Prostate-Specific Antigen

Despite controversy over its correlation with prostate cancer volume (Stamey et al, 2004), PSA level is associated directly with pathologic stage and tumor extent (Stamey et al, 1987, 1989). PSA value cannot be used alone to accurately predict disease extent for an individual patient because of significant overlap in PSA levels between stages, the variable contribution from BPH to PSA, and the fact that—on average—poorly differentiated tumors produce less PSA per gram of tumor (Partin et al, 1990). Despite these confounding factors, pathologically organ-confined disease is found in 80% of men with a PSA less than 4.0 ng/mL, 66% of those with PSA levels between 4.0 and 10.0 ng/mL, and fewer than 50% of men with PSA levels greater than 10.0 ng/mL (Catalona et al, 1997; Rietbergen et al, 1999). Also, 20% of men with PSA levels greater than 20 ng/mL and 75% of those with PSA levels greater than 50 ng/mL are found to have pelvic lymph node involvement.

In addition to the tPSA level, fPSA, hK2, proPSA, PSAD, and PSAV (see earlier discussion) have been evaluated as predictors of prostate cancer grade and extent (Carter et al, 1997b; Southwick et al, 1999; D'Amico et al, 2004, 2005; Carter et al, 2006, 2007; Kundu et al, 2007; Loeb et al, 2008d). Although prostatic acid phosphatase has been associated with pathologic stage and progression after radical prostatectomy (Moul et al, 1998; Han et al, 2001) the closer relationship between PSA level and disease extent has virtually eliminated the clinical use of this parameter (Heller, 1987).

Digital Rectal Examination

DRE is used to determine whether a lesion is palpable and is associated with local disease extent (clinical T stage). Also, an abnormal DRE was associated with an increased risk for detecting high-grade (Gleason 8 to 10) prostate cancer in a screened population (Gosselaar et al, 2008).

However, because of its poor sensitivity and lack of reproducibility, DRE can both overestimate and underestimate the extent of disease (Turner and Belt, 1957; Byar and Mostofi, 1972; Walsh and Jewett, 1980). In one series of 565 men with presumed organ-confined disease based on DRE, the sensitivity and specificity were 52% and 81%, respectively, for prediction of organ-confined disease (Partin et al, 1993b). Nevertheless, DRE can be used in combination with other parameters to help predict tumor extent.

Prostate Needle Biopsy

Histologic grade is the most important information obtained from prostate needle biopsy, and the Gleason grading system is the most commonly used (Gleason, 1966). At low-power magnification, the sum of a grade (1 to 5) assigned to the predominant pattern (occupying the largest area of the specimen) and the second most common pattern yield a score ranging from 2 to 10.

Contemporary studies have shown that tertiary Gleason patterns may affect prognosis (Patel et al, 2007), leading a 2005 consensus conference to recommend modification of the Gleason grading system (see Chapter 110). Accordingly, a biopsy Gleason score of 3 + 4 or 4 + 3 with a tertiary pattern 5 would be considered Gleason 3 + 5 or 4 + 5, respectively (Epstein et al, 2005). Recently, debate regarding the biologic potential of Gleason 6 tumors led to the suggestion of an alternative classification system, in which Gleason scores of 6 or less, 3 + 4 = 7, 4 + 3 = 7, 8, and 9 and 10 would be labeled as Gleason score prognostic grade groups 1 to 5 (Carter et al, 2012).

Although a higher Gleason grade is associated with worse prognosis, it is not used alone for risk prediction (Stein et al, 1991; Epstein et al, 1993a, 1993b; Partin et al, 1993a; Zincke et al, 1994). Other biopsy findings provide information regarding the extent of disease, including the number of positive cores, percentage of positive cores, and presence of perineural invasion. These features are associated with radical prostatectomy findings and have been used

to guide the selection of candidates for active surveillance programs (Egan and Bostwick, 1997; de la Taille et al, 1999a; Carter et al, 2002; O'Malley et al, 2002; Bismar et al, 2003).

Findings of seminal vesicle invasion or involvement of the periprostatic fat on prostate needle biopsy are associated with worse prognosis (Stone et al, 1998). Although some authors have recommended biopsy of the seminal vesicles and/or prostatic capsule to improve staging (Terris et al, 1993; Ravery et al, 1994; Vallancien et al, 1994; Stone et al, 1995, 1998), others suggest biopsy of these structures only when there is a large palpable tumor located at the base of the prostate (Guillemot et al, 1997; Terris et al, 1997).

Combined Use of Pretreatment Parameters

Nomograms and algorithms have been developed to integrate multiple clinical parameters for improved staging. Considering the primary T stage based on DRE findings, serum PSA level, and Gleason grade, these algorithms and nomograms have been shown to more accurately predict both cancer extent and long-term outcomes after treatment compared to any single parameter (Humphrey et al, 1991; Kleer and Oesterling, 1993; Kleer et al, 1993; Partin et al, 1993b, 1997, 2001; Kattan et al, 1998; Han et al, 2003; Stephenson et al, 2006; Makarov et al, 2007).

Several classification schemes have been proposed that correlate with clinical outcomes. D'Amico and associates (1998, 2001) demonstrated that stratification into low-risk (clinical stage T1 to 2a, PSA ≤ 10 ng/mL and Gleason score ≤ 6), intermediate-risk (stage T2b or PSA > 10 but < 20 ng/mL or Gleason score 7), and high-risk disease (stage T2c, or PSA > 20 ng/mL or Gleason score 8 to 10) was significantly associated with freedom from disease at 10 years after radical prostatectomy; 83% for low-risk, 46% for intermediate-risk, and 29% for high-risk disease. Other validated classification schemes have been developed since, including the Cancer of the Prostate Risk Assessment (CAPRA) score (Cooperberg et al, 2005, 2006; May et al, 2007). Pretreatment risk stratification using multiple parameters is useful for patient counseling.

Imaging

Numerous imaging modalities have been evaluated for staging prostate cancer. Radionuclide bone scan (bone scintigraphy) is the most commonly employed modality for the detection of skeletal metastases (Terris et al, 1991). Bone survey films (skeletal radiography) have lower sensitivity for the identification of distant spread and are typically used only to confirm a positive bone scan in men at low risk for bone metastases. Because bone metastases at diagnosis are rare in asymptomatic men in the PSA era, the routine use of bone scans in this population may lead to false-positive results, as well as unnecessary anxiety and cost (Chybowski et al, 1991). Accordingly, recent guidelines recommend the use of bone scans for patients with a PSA level greater than 20 ng/mL, Gleason score of 8 to 10, clinical stage T3 or T4, or clinical symptoms. By contrast, the Choosing Wisely Campaign recently has emphasized that routine bone scans are not necessary for men with low-risk prostate cancer (American Urological Association, 2013b).

Similarly, cross-sectional imaging to evaluate for lymphadenopathy is recommended for high-risk patients, such as those with clinical stage T3 or greater disease or greater than 20% nomogram probability of lymph node metastases. Given the rarity of lymph node involvement in contemporary screened populations, it appears that imaging is being overused (Kindrick et al, 1998; Cooperberg et al, 2002; Abraham et al, 2007).

Although magnetic resonance imaging (MRI) has been evaluated for staging prostate cancer for many years (Yu et al, 1999; Kurhanewicz et al, 2000) the technology has recently improved dramatically. In particular, the addition of functional sequences such as diffusion-weighted MRI and dynamic contrast-enhanced MRI in conjunction with the conventional T2-weighted MRI has improved the ability of MRI to characterize the locoregional extent of disease. It is currently used at some institutions for pretreatment planning before definitive local therapy or to assess candidacy for active

surveillance (Vargas et al, 2012; Somford et al, 2013). In addition, MRI images may be fused with TRUS to enable targeted prostate biopsy—for example, in patients with previous negative TRUS-guided biopsies (Sonn et al, 2014; Siddiqui et al, 2015).

Specialized techniques such as high-resolution MRI used in tandem with the intravenous administration of lymphotropic superparamagnetic nanoparticles may allow the detection of small and otherwise undetectable lymph node metastases in patients with prostate cancer (Harisinghani et al, 2003). These techniques, however, require further clinical evaluation before widespread use.

Advances in ultrasound imaging also are being studied for improving prostate cancer detection (Purohit et al, 2003). Color ultrasonography with power Doppler to evaluate the blood flow within prostate vessels and three-dimensional (3D) Doppler using contrast agents could improve the visualization of more subtle tissue alterations caused by cancer. Another new ultrasound-based technique is HistoScanning (BK Medical, Peabody, MA), a computer-aided process to help characterize potentially suspicious tissue (Simmons et al, 2012). Additional large-scale studies of these techniques are necessary before widespread use can be recommended.

Finally, monoclonal antibody radioimmunoscintigraphy (radio-labeled monoclonal antibody scan) has been used for identification of microscopic cancer deposits in regional and distant sites. The ProstaScint scan (Cytogen, Princeton, NJ) uses this technology but has had limited accuracy in the detection of lymph node metastases because the antibody targets an intracellular epitope that is exposed only in dying or dead cells (Troyer et al, 1997; Chang et al, 1999). Future generations of this technology circumventing this limitation are under development.

Molecular Staging

Molecular staging has focused on the detection of circulating prostate cancer cells either directly through centrifugation/immunostaining methods or indirectly by identifying the genetic material for prostate-specific biomarkers (e.g., PSA, prostate-specific membrane antigen) from circulating prostate cells (Moreno et al, 1992; Ts'o et al, 1997). Although these polymerase chain reaction (PCR)-based assays have been associated with pathologic stage, sensitivity for detecting circulating cancer cells is variable across studies (Cama et al, 1995; Israeli et al, 1995; de la Taille et al, 1999b). With the FDA approval of the semiautomated CellSearch system (Veridex, Janssen Diagnostics, Raritan, NJ) for monitoring metastatic breast and prostate cancer, considerable investigation is underway to determine whether circulating tumor cells have a role in the staging of early disease (Davis et al, 2008; Helo et al, 2009).

Several new tissue-based tests have been introduced that may improve prostate cancer risk stratification. The Prolaris test (Myriad Genetics, Salt Lake City, UT) measures a panel of cell cycle progression genes involved in the process of cancer proliferation (Cooperberg et al, 2013). The Oncotype DX Prostate Cancer Test (Genomic Health, Redwood City, CA) is a quantitative RT-PCR assay for 17 genes involved from five different pathways involved in prostate carcinogenesis (Knezevic et al, 2013). Preliminary studies of these tests suggest a potential ability to further refine classification schemes beyond the standard risk groups (Klein et al, 2014); however, further prospective validation studies are necessary to demonstrate whether these tests are cost effective.

Pelvic Lymphadenectomy

The presence of lymph node metastasis in men diagnosed with clinically localized prostate cancer portends a worse prognosis. Identification of patients harboring nodal metastases could have important implications for treatment selection. Although the prevalence of pelvic lymph node metastases correlates directly with T stage, serum PSA level, and biopsy grade, pelvic lymphadenectomy remains the most accurate way to detect occult nodal involvement (Parker et al, 1999).

PSA screening has resulted in a steady decline in the rates of metastases from 20% to 40% in the 1970s and 1980s to less than

4% today (Partin et al, 1997; Parker et al, 1999; National Cancer Institute, 2013). Currently, lymphadenectomy often is omitted before curative treatment (e.g., radical prostatectomy, radiation therapy) (Bishoff et al, 1995; Kawakami et al, 2006). Laparoscopic pelvic lymphadenectomy before treatment is typically reserved for patients with Gleason score greater than 8, extraprostatic extension on DRE, PSA value greater than 20 ng/mL, or suspicion of enlarged lymph nodes on radiologic evaluation and is rarely performed in the contemporary PSA era.

Given the individual variation in prostatic lymphatic drainage patterns (Mattei et al, 2008), some investigators favor an extended pelvic lymphadenectomy in lieu of a limited dissection (Bader et al, 2002; Burkhard et al, 2006). Considering the greater complication rates with a more extended pelvic lymph node dissection, risks may outweigh benefits for most men diagnosed with low-risk cancer today (Klein et al, 2008). Information regarding the therapeutic value of these strategies is confounded by stage migration and is difficult to evaluate without prospective trials.

KEY POINTS: DIAGNOSIS AND STAGING OF PROSTATE CANCER

- Although the value of PSA screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test so they can make an informed decision about the need for routine screening.
- The combination PSA level, DRE, and other clinical factors (e.g., age, race, family history) can be used in combination to predict the risk that prostate cancer is present. The presence of prostate disease (prostate cancer, BPH, and prostatitis) is the most important factor affecting serum levels of PSA.
- PSA testing increases detection rates of prostate cancer and leads to the detection of prostate cancers that are more likely to be organ-confined when compared with detection without the use of PSA.
- The future risk for prostate cancer detection and the chance of finding cancer on a prostate biopsy increase incrementally with the serum PSA level.
- Biochemical recurrence-free survival and cancer-specific survival are both inversely related to the pathologic stage of disease.
- Pathologic criteria that predict prognosis after radical prostatectomy are tumor grade, surgical margin status, presence of extracapsular disease, seminal vesicle invasion, and pelvic lymph node involvement.
- The Gleason grading system is the most commonly used classification scheme for the histologic grading of prostate cancer.

Background

Established Treatments

Other Treatments

Recommendations for Treatment by Patient Risk Group

The purpose of this chapter is to provide an overview of the management of clinically localized prostate cancer. In reporting differences in treatments, we have attempted to be objective but have included our editorial perspective. For balance, we have included in our suggested reading list several recent articles focusing on the relative advantages and disadvantages of the different management strategies, some expressing opinions contrary to ours. We have grouped treatments into *established treatments*, such as radical prostatectomy and radiotherapy, for which abundant published information is available, and *other treatments*, including active surveillance, primary hormone therapy, cryoablation, radiofrequency ablation, and high-intensity focused ultrasound (HIFU), for which data are more limited for localized disease.

BACKGROUND

Prostate cancer is the most common nonskin cancer and the second-leading cause of death from cancer in men in the United States. In 2014, it was estimated that 233,000 new cases would occur; it would be the cause of death for 29,480 men (Siegel et al, 2014). Because prostate cancer is prevalent in many countries and exhibits a wide spectrum of aggressiveness, different methods of treatment have been developed, and the preferred methods for detection and treatment are controversial. The prevalence of prostate cancer increases strikingly with age. Autopsy studies have documented microscopic foci of prostate cancer in about one fourth to one third of men in the fourth and fifth decades of life and in more than three fourths in the ninth decade (Sakr et al, 1993; Yin et al, 2008). Yet a disproportionately lower but still substantial number of men (about one in seven) are diagnosed with prostate cancer during their lifetime (Siegel et al, 2014). Because of effective treatment of some prostate cancers and the biologic indolence relative to life expectancy of others, only about 16% of men diagnosed with prostate cancer ultimately die of it. Prostate cancer is the cause of death in about 3% of the U.S. male population (Siegel et al, 2014). An additional unquantified proportion of men have prostate cancer-related morbidities but die of other causes.

The marked disparity between prevalence and incidence rates of prostate cancer on one hand and morbidity and mortality rates on the other has led some to conclude that many prostate cancers are harmless and perhaps would better be left undetected. Nevertheless, if the present trends of increasing life expectancy continue, given the current age-specific incidence, morbidity, and mortality rates of prostate cancer, this disease will become a far greater public health problem in the future (Li and Ekwueme, 2010). In the U.S. national Surveillance, Epidemiology, and End Results (SEER) Program database, the prostate cancer incidence was increased for

younger men whereas it was decreased in older men. Also, the incidence of poorly differentiated tumors increased whereas the incidence of well-differentiated tumors decreased significantly (Li and Ekwueme, 2010). Therefore, prostate cancer is being diagnosed in younger men, with more frequent diagnosis of those likely to benefit from treatment.

Since the 1980s, the methods of diagnosis of clinically localized prostate cancer have changed. Widespread screening with serum prostate-specific antigen (PSA) and digital rectal examination (DRE) has allowed earlier detection (Catalona et al, 1991; Catalona, 1993). Furthermore, with a remarkable stage migration, approximately 81% of cases are being detected at a clinically localized stage; metastases at the time of diagnosis are now rare in the United States (4%) as well as in Europe (Han et al, 2001a; Gallina et al, 2008; Siegel et al, 2014). The natural history of prostate cancer varies from indolent disease that might not cause symptoms during a patient's lifetime to highly aggressive cancer that metastasizes quickly and causes terrible suffering and untimely death. The challenge for the physician who manages patients with prostate cancer is to advise effective treatment in those for whom treatment is necessary. Selection of the appropriate treatment requires assessment of the tumor's potential aggressiveness and the general health, life expectancy, and quality-of-life preferences of the patient.

Patients whose tumor has a low malignant potential are predetermined to fare better with most treatments. Therefore, the treatment outcomes in any patient series may be influenced by the malignant potential of the tumors as well as by the treatment used. Accordingly, it is difficult to compare the results of different treatments because the populations of patients are usually heterogeneous and not strictly comparable. Furthermore, outcome measurements are not necessarily comparable among different forms of therapy (e.g., different definitions of biochemical progression for surgery and radiotherapy), confounding comparisons among them.

Prostate Cancer Screening

The conflicting results of two prospective, randomized trials of screening for prostate cancer from Europe and the United States have created controversy over the risks and benefits of early prostate cancer detection and definitive treatment (Andriole et al, 2009; Schroder et al, 2009). The European trial (European Randomized Study of Screening for Prostate Cancer [ERSPC]), which was twice as large and had less contamination with opportunistic screening of the control arm (PSA testing was not as widespread in Europe as in the United States at the time), used a screening interval of 4 years with a PSA cutoff of 3 ng/mL at most sites and

included a DRE during the first or second round of screening. The European trial showed that screening decreased the prostate cancer mortality rate by 20% (27% in men who were actually screened) (Schroder et al, 2009). The survival curves began to diverge at 6 to 7 years and continued to diverge at the time of the report. There was a 71% increase in the number of cancers detected in the screening arm and a 41% decrease in incurable disease at diagnosis. In this initial report, the authors estimated that 1400 men would have to be screened and 48 treated to save one life (Schroder et al, 2009; Gulati et al, 2011). In updated results at a median follow-up of 11 years, there was a 21% decrease in prostate cancer-specific mortality, and the same authors estimated that 1055 men would need to be screened and 37 cancers would need to be detected for prevention of one death from prostate cancer (Schroder et al, 2012b). Subsequently, based on the same ERSPC data, it was estimated that annual screening of men in the ERSPC aged 55 to 69 years would result in a 28% reduction in prostate cancer deaths (37% in those actually screened). The estimated number needed to screen to prevent one prostate cancer death was 98, and the number of cancers needed to be detected was five (Heijnsdijk et al, 2012). In a reanalysis of ERSPC data, Hanley pointed out that in estimating the reduction of overall average mortality, the ERSPC authors included the initial years of zero effect. This provides a diluted measure of the impact of screening. Assuming steady-state screening using the ERSPC protocol, Hanley estimated that there would be a 67% decrease in prostate cancer-specific mortality at 12 years of follow-up (Hanley, 2011).

The independent Göteborg population-based randomized screening trial screened younger men (aged 50 to 64), screened every 2 years, used lower PSA cutoffs of biopsy (3.4 ng/mL progressing to 2.5 ng/mL), and had only 3% screening of controls; 93% complied with a biopsy recommendation, and 77% had 14-year follow-up (Hugosson et al, 2010). In the screening arm there were 41% fewer advanced cases at diagnosis and a 44% lower prostate cancer-specific mortality rate that was significant across all age groups and was greatest in the youngest patients. In this trial, one third of patients were managed with active surveillance. In current empirical data from the Göteborg trial with 16 years of follow-up, the number needed to screen to avoid one prostate cancer death is 208 and the number needed to treat is 9 (Carlsson, personal communication, 2013).

The U.S. trial (Prostate, Lung, Colorectal and Ovarian [PLCO] Cancer Screening Trial) of annual screening for 6 years with PSA and DRE showed no effect in the entire cohort at 7 years and no substantial increase in cases detected or decrease in incurable cases (Andriole et al, 2009). The results were released prematurely, just as the ERSPC trial was reporting that PSA screening saves lives, because of concerns by the PLCO study monitoring committee that screening showed no benefit, to offset the potential harms associated with treatment. A subsequent update of the PLCO trial continued to show no mortality difference in prostate cancer mortality in the entire cohort at 13 years (Andriole et al, 2012). However, the PLCO trial had severely limiting flaws:

1. Approximately 40% of the participants had been prescreened with PSA.
2. A higher PSA cutoff (4 ng/mL) was used.
3. In the control arm, 85% of the participants had had at least one PSA measurement, and in 96% of these, testing had taken place in the previous 2 to 3 years. In the screening arm of the PLCO trial, 85% of patients were tested during the study and as a group had more PSA tests (Pinsky et al, 2010).
4. In the screening arm, most patients with abnormal screening results did not undergo prompt biopsy.
5. The study was underpowered to demonstrate a mortality benefit of screening.

However, in a subset analysis of the PLCO trial (Crawford et al, 2011), a 44% decrease in the risk of prostate cancer-specific death was observed in the screening arm in men with no or minimal comorbidity, and the numbers needed to screen and treat to

prevent one death were 723 and 5, respectively. This benefit was not found among men with more significant comorbidities (Andriole et al, 2012).

Based on new evidence on the benefits and harms of PSA-based prostate cancer screening, the U.S. Preventive Services Task Force (USPSTF) in 2012 recommended against PSA-based screening in the general U.S. population, regardless of age or race (Moyer and USPSTF, 2012). However, USPSTF overestimated harms and underestimated benefits of PSA-based screening, with undue weight given to the PLCO trial and the Prostate Cancer Intervention versus Observation Trial (PIVOT). This recommendation also ignored the high-risk men with a family history of prostate cancer or those with African ancestry. In addition, reduction in metastatic disease as a result of PSA-based prostate cancer screening was not weighed against the side effects from treatment (Hartzband and Groopman, 2012; Scosyrev et al, 2012b). Screening dramatically reduced metastases at diagnosis in the ERSPC and Göteborg trials (Schroder et al, 2012a). The USPSTF recommendation has had a transformative effect because it changed the default option for prostate cancer screening. Research in cognitive science has shown that the default option transmits a powerful message to the public about how to weigh risk and benefit of screening (Hartzband and Groopman, 2012). Nevertheless, in spite of this USPSTF recommendation against screening, PSA-based screening continues to be recommended by physicians (Colbert and Adler, 2012). After reviewing the same evidence that the USPSTF reviewed, virtually all other professional organizations, including the American Cancer Society, American College of Physicians, American Society of Clinical Oncology, American Urological Association (AUA), European Association of Urology, and the 2013 Prostate Cancer World Congress recommend PSA testing for selected men with a shared decision making process (Basch et al, 2012; Carter et al, 2013; Heidenreich et al, 2013; Qaseem et al, 2013; Murphy et al, 2014; Smith et al, 2014). Moreover, the National Comprehensive Cancer Network (NCCN) provides guidelines for early prostate cancer detection in men who have elected to be screened (NCCN, 2014).

Pound and colleagues reported that the median time from PSA failure to the development of metastases after radical prostatectomy is 8 years and the median time from metastases to death is 5 years (Pound et al, 1999). Thus, the median time from diagnosis to death is more than 13 years. In the European trial there was no improvement in survival until after 7 years, confirming that a long observation period is necessary to assess the treatment outcomes in prostate cancer.

The United States trial has been portrayed as the underpinning for a proposed shift in the mindset of physicians and patients that screening for and treatment of prostate cancer do more harm than good. However, this trial was flawed at the beginning and will never be informative of the true impact of screening on prostate cancer death of healthy men managed with intelligent screening, prompt biopsy, and effective treatment.

There is other compelling evidence to suggest that early diagnosis through PSA testing and prompt, effective, and high-quality treatment save lives. This evidence comes largely from the cancer registries of the United States and World Health Organization databases. The percentage of men who have advanced prostate cancer at the time of diagnosis has decreased by 80% in the United States during the PSA era, and there has been a 45% decrease in the prostate cancer death rate during the PSA screening era (Boring et al, 1991; National Cancer Institute, 2014; Siegel et al, 2014). Using statistical modeling, Etzioni and colleagues (2008, 2012) estimated that the improvements in treatment explained 22% to 33% of the mortality decline, whereas the remainder of the decline probably was a result of other interventions, such as PSA-based prostate cancer screening.

Other studies have shown that in regions of the United States where more PSA testing is performed, there are lower rates of advanced prostate cancer and prostate cancer death (Colli and Amling, 2008). In a population-based study, PSA screening reduced the prostate cancer-specific mortality rate by 62% (Agalliu et al, 2007; Kvale et al, 2007). Globally, the death rate also has fallen

in countries where PSA testing is practiced, whereas it continues to rise in countries where it is not (Bouchardy et al, 2008).

The frequently cited decrease in prostate cancer mortality reported in the United Kingdom from 1992 to 2004 in the absence of widespread PSA screening is largely a result of the method of attributing the cause of death in the United Kingdom databases during that time. Before the PSA era, if a man with metastatic prostate cancer died of pneumonia, the cause of death was attributed to prostate cancer, but during the early years of the PSA era, the cause of death was attributed to pneumonia. Thus there was a spurious decrease in the prostate cancer mortality rate in the PSA era in the absence of widespread PSA screening (Hussain et al, 2008).

Characterization of the Primary Tumor

DRE and prostate ultrasound findings usually provide useful information about the extent of the primary tumor. The serum PSA data, including the total PSA level, the rate of change of PSA (PSA velocity and doubling time), the PSA density (serum PSA divided by prostate volume), the percentage of PSA in the free or complexed isoforms, and the Prostate Health Index are significantly associated with prostate cancer aggressiveness (Benson et al, 1992; Carter, 1997; Catalona et al, 1998; D'Amico et al, 2004; Thompson et al, 2004; Kundu et al, 2007; Catalona et al, 2011). The biopsy findings (Gleason score; the number of cores containing cancer; the distribution and volume of cancer in the biopsy cores; the presence of perineural space invasion, lymphovascular invasion, ductal, signet ring, or neuroendocrine differentiation) also correlate with cancer aggressiveness and the likelihood of the cancer's being organ confined (Loeb et al, 2010a). Prediction tables and algorithms have been developed to assist in this assessment (Partin et al, 1997, 2001; Makarov et al, 2007; Eifler et al, 2013). However, such statistical aids are more useful in groups of patients than in individual patients, and wide confidence intervals surrounding estimates of outcomes may limit the usefulness of risk assessment for an individual patient. Accordingly, it has been claimed that the simultaneous assessment of multiple variables in nomograms provides more accurate predictions than do tables for individual patients (Kattan, 2003).

Evaluation of the Patient

There is a general consensus about how extensive the initial staging workup should be. A radionuclide bone scan, abdominal-pelvic computed tomography (CT) scan, and magnetic resonance imaging (MRI) scan are not indicated if the tumor has a Gleason sum of less than 7 (or in some guidelines, 8) (NCCN, 2014), the serum PSA level is less than 10 ng/mL, and the biopsy findings do not reveal an extensive or highly aggressive cancer, because the likelihood of finding metastases is quite low. AUA and NCCN guidelines recommended avoiding a routine radionuclide bone scan in men with low-risk prostate cancer who have a PSA below 20 ng/mL and a Gleason score of 6 or less unless there is a suggestion of bony involvement.

In higher-risk patients contemplating surgical treatment, a more complete workup should be considered, including coagulation studies, if appropriate, a nuclear bone scan, and CT or MRI scan of the abdomen and pelvis to evaluate the primary tumor and regional lymph nodes and to rule out other possibly important conditions that might need to be addressed at the time of surgery. However, tumor-selective imaging tests such as monoclonal antibody scans, positron emission tomographic scans, magnetic resonance spectroscopy, and lymphotropic MRI are not widely used, although they might prove more useful in the future. Thus, with increasing availability of MRI technology with diffusion-weighted imaging (DWI) and dynamic contrast enhancement (DCE) and the MRI-ultrasound fusion biopsy technique, there is increasing use of MRI to help improve accuracy of biopsy and to evaluate the local extent of the tumor (Hambrock et al, 2008; Liauw et al, 2013; Mullins et al, 2013; Siddiqui et al, 2013).

ESTABLISHED TREATMENTS

Conservative Management

Active Surveillance or Watchful Waiting

Active surveillance and *watchful waiting* are almost unique to prostate cancer. *Watchful waiting* refers to monitoring the patient until he develops metastases that require palliative treatment. *Active surveillance* or *expectant management* allows delayed primary treatment if there is biochemical or histologic evidence of cancer progression (Dall'Era et al, 2012). Active surveillance is a less established strategy in patients with a long life expectancy because criteria for selecting candidates and trigger points for instituting treatment have yet to be defined and validated. Currently, treatment is frequently initiated because of the patient's anxiety from living with untreated cancer combined with a rising PSA level or biopsy findings that suggest an increase in the volume or Gleason grade of the cancer.

Traditionally, deferred treatment has been reserved for men with a life expectancy of less than 10 years and a low-grade (Gleason score 2 to 6) prostate cancer. However, active surveillance is now being evaluated as a management strategy in younger patients with low-volume, low- or intermediate-grade (up to Gleason score $3 + 4 = 7$) tumors to avoid or to delay treatment that might not be immediately necessary. In one study, approximately 16% of patients with newly diagnosed prostate cancer would fulfill the criteria for active surveillance, about 10% chose surveillance, and an additional 4% who did not meet all criteria chose surveillance (Barocas et al, 2008). According to a more recent analysis, there has been a significant and steady rise in active surveillance since 2008; in 2011, 18.6% of patients with low-risk prostate cancer were receiving expectant management (Charnow, 2014).

In the very long-term follow-up (>30 years), there is a significant risk of cancer progression and prostate cancer-specific death in men with untreated localized prostate cancer (Popiolek et al, 2013). In this study, local progression (41%) and distant metastasis (18%) developed from localized prostate cancer.

Certain populations should be approached with an even greater level of caution when considering active surveillance. In African-American men, the progression risk was significantly increased in active surveillance (Iremashvili et al, 2013). In addition, African-American men who were candidates for active surveillance criteria had worse clinicopathologic features on final surgical pathology than Caucasian men (Abern et al, 2013; Ha et al, 2013; Iremashvili et al, 2013; Sundi et al, 2013). Also, patients with BRCA2 mutations have higher Gleason scores, more advanced tumor stage, and shorter median survival (Castro et al, 2013; Bancroft et al, 2014). Therefore they are not suitable candidates for active surveillance.

Statistical models have been generated in an attempt to predict which tumors can be observed without aggressive treatment. For example, Epstein and associates proposed a model involving preoperative clinical and pathologic features that would predict "insignificant tumors" (tumor volume less than 0.2 mL, Gleason score below 7, and organ-confined cancer) (Epstein et al, 1994, 1998). The preoperative features used in the model include no Gleason pattern 4 or 5 in the biopsy specimen, PSA density of 0.1 ng/mL/g or less, fewer than three biopsy cores involved (with a minimum of six total cores being obtained), no core with more than 50% involvement or PSA density of 0.1 to 0.15 ng/mL/g, and cancer smaller than 3 mm on only one prostate biopsy sample. Characteristically for statistical models, this model was reported to have a predictive value of 95% for identifying a "significant" cancer but a predictive value of only 66% for identifying an "insignificant" cancer (Epstein et al, 1994). Approximately 16% of the men in this series met criteria for an insignificant cancer (Epstein et al, 1994). Subsequently, Epstein and colleagues updated the model to include a free/total PSA ratio (0.15) and favorable needle biopsy findings (fewer than three cores involved, no core with more than 50% tumor, and Gleason score of 6 or lower) (Epstein et al, 1998).

Kattan and associates proposed another statistical model to predict small, moderately differentiated, organ-confined cancer on the basis of PSA, clinical stage, biopsy Gleason score, ultrasound-determined prostate volume, and variables derived from systematic biopsies (Kattan, 2003). They defined indolent cancer as being organ confined, less than 0.5 mL tumor volume, without poorly differentiated elements. Approximately 20% of their patients treated with radical prostatectomy met the criteria for indolent tumors according to their prediction model.

When the outcomes of men who underwent radical prostatectomy but would have otherwise been candidates for active surveillance were examined, 20% to 50% had Gleason score of 7 or above and/or extraprostatic disease, even with the most stringent criteria for selection (Suardi et al, 2008; Thaxton et al, 2010; Vellekoop et al, 2014). Some authors have claimed that even patients who do not fulfill such criteria may be legitimate candidates for active surveillance (Epstein et al, 1998; Reese et al, 2013). However, studies of active surveillance for men in different strata of low- and intermediate-risk prostate cancer suggest that there is proportionately more upgrading and upstaging in higher risk strata (Cooperberg et al, 2011). A potential untoward consequence of recommending active surveillance for all men who do not have obviously aggressive, clinically localized disease is that only men with clearly aggressive and often incurable disease would be treated immediately, whereas a substantial proportion of those with curable disease destined to progress would be managed with surveillance, often with multiple extended biopsy procedures that could contribute to infections, cause erectile dysfunction, complicate subsequent attempts at nerve-sparing surgery, and delay treatment until the window of opportunity for cure had closed (Fujita et al, 2009).

All prostate cancer patients are at risk for progression. In reports of active surveillance, patients are usually observed with semiannual PSA determinations and DRE and annual biopsies (Zietman et al, 2001; Choo et al, 2002; Klotz, 2003; el-Geneidy et al, 2004; Patel et al, 2004; Carter et al, 2007; Dall'Era et al, 2012). Intervention is recommended if Gleason pattern 4 or 5 is present, more than two biopsy cores are involved, or more than 50% of a biopsy core is involved. Progression is more likely in patients who have cancer present on every biopsy procedure. The absence of cancer on repeated biopsy significantly decreases the likelihood of progression (Carter et al, 2007). Accordingly, biopsy criteria have been reported to be more accurate than PSA criteria in predicting progression (Ross et al, 2010). Perineural invasion on biopsy during active surveillance is not associated with adverse pathologic outcomes (Al-Hussain et al, 2011). No study has found DRE or imaging studies to independently predict progression. Recent studies have suggested that the [−2] proPSA and PSA velocity risk count are associated with an increased risk of reclassification on active surveillance (Tosoian et al, 2012; Patel et al, 2014).

The percentage of patients with curable cancer at the time of progression has been reported to vary from 33% to 92%. In most studies of active surveillance, approximately 25% to 50% of patients, depending on their individual risk factors, develop objective evidence of tumor progression within 5 years (Neulander et al, 2000; Patel et al, 2004; Warlick et al, 2006; Duffield et al, 2009). Carter and colleagues reported that 59% remained on surveillance, 25% underwent curative treatment, and 16% withdrew, were lost to follow-up, or died of other causes (Carter et al, 2007). With a longer follow-up of the same cohort, Tosoian and associates reported that only 41% remained on active surveillance at 10 years. There were no prostate cancer deaths, although the follow-up was too short to assess mortality in this cohort with strict criteria for active surveillance (Tosoian et al, 2011). Although some studies suggest that most patients with Gleason score 6 or lower tumors do not suffer or die of prostate cancer with conservative management, those with higher Gleason score tumors have a substantial risk for morbidity and mortality (Albertsen et al, 1995; Johansson et al, 2004). Klotz and colleagues reported that of patients who underwent radical prostatectomy for evidence of

cancer progression during active surveillance, 58% had tumor extension beyond the prostate, and 8% had lymph node metastases (Klotz, 2006, 2009). In this series of men treated with surgery or radiotherapy for progression on active surveillance, the 5-year progression-free survival rate was only 47% (Klotz, 2009). Among the five early patients who died within 4 to 10 years of diagnosis, four had Gleason grade 6 disease at diagnosis and two met the Epstein criteria for “insignificant” cancer (Krakowsky et al, 2010).

A prospective, randomized clinical trial from Scandinavia reported that at 18 years of follow-up, rates of overall and prostate cancer-specific mortality as well as distant metastases and disease progression were significantly higher in patients managed with watchful waiting than in those treated immediately with radical prostatectomy (Bill-Axelsson et al, 2014). The number needed to treat to save one life was 8 overall and 4 in men younger than 65 years.

Early detection and treatment of organ-confined disease in younger men with longer follow-up are important factors in lowering the number needed to treat even further. Similarly, an observational study of Medicare patients treated with observation, radiation, or surgery showed a survival advantage for active treatment of men aged 65 to 80 years; however, the absolute difference in cancer-specific death at 12 years was small (Wong et al, 2006). Similarly, using the SEER Medicare-linked database, Abdollah and associates reported that radical prostatectomy decreases the risk of prostate cancer-specific mortality by half compared with observation in men older than 65 years (Abdollah et al, 2011).

In the recent Veterans Affairs Cooperative Studies Program PIVOT study, Wilt and colleagues reported that radical prostatectomy did not significantly reduce all-cause or prostate cancer-specific mortality, as compared with observation (Wilt et al, 2012). In men with prediagnosis serum PSA level higher than 10 ng/mL, there was an absolute risk reduction for prostate cancer-specific and all-cause mortality with treatment. In contrast, mortality was not significantly reduced in men with PSA lower than 10 ng/mL or in those with low-risk tumors. However, there was 60% decrease in metastasis rate and 37% decrease in prostate cancer-specific mortality rate in the radical prostatectomy arm. PIVOT was underpowered to detect a difference in survival and was conducted in Veterans Affairs hospitals where many men had relatively poor health. In addition, radical prostatectomies were performed with higher complication rates with worse cancer control outcomes compared with the series from the centers of excellence. In addition, a median follow-up of 10 years is insufficient to assess the mortality caused by prostate cancer. Therefore, using the PSA cutoff of 10 ng/mL for screening for prostate cancer as suggested by the PIVOT investigators would most likely result in more advanced prostate cancer at diagnosis and lead to a poorer prognosis. In contrast to the PIVOT study, in the Scandinavian Trial, intermediate-risk patients had the greatest benefit from radical prostatectomy and there was no benefit in high-risk patients (Bill-Axelsson et al, 2014).

One rationale for active surveillance is the belief that there is substantial overdiagnosis of prostate cancer as a result of widespread PSA screening coupled with aggressive biopsy regimens. *Overdiagnosis* often refers to a cancer detected by screening that would not be detected during the patient's lifetime without screening or would never cause disability or death (Loeb et al, 2014). It is axiomatic that any effort to detect cancer early will involve detection of some cancers that would not have been otherwise detected. Therefore, some overdiagnosis is necessary to reduce suffering and death from prostate cancer.

There are two methods of estimating the extent of overdiagnosis. The epidemiologic method applies only to populations, not to individuals. With this method, statisticians look at population trends in prostate cancer cases and use statistical models to estimate whether more cases are being diagnosed than should be, considering past incidence rates of prostate cancer and prostate cancer deaths. Statisticians estimate lead time in prostate cancer diagnosis with PSA screening (3 to 12 years) and use the lead time to estimate overdiagnosis; however, statistical models have not accurately

predicted the observed incidence of prostate cancer nor fully explained the observed decrease in advanced disease.

The second method of estimating overdiagnosis is for a pathologist to examine a surgically removed cancerous prostate gland and determine whether it contains only a tiny amount of cancer that has no high Gleason pattern glands and that is completely encapsulated within the prostate gland. If so, it is designated as an overdiagnosed cancer.

Some reports have estimated that 50% or more of prostate cancer cases are overdiagnosed (Etzioni et al, 2002; Draisma et al, 2003). However, recent studies suggest that epidemiologic estimates of overdiagnosis are exaggerated. Epidemiologic estimates based on statistical models from the United States and using data from the United States yield a 23% to 28% incidence of possible overdiagnosis (Draisma et al, 2009). Estimates in surgically treated patients based on clinicopathologic data range from 6% to 20% (Graif et al, 2007; Pelzer et al, 2007).

Estimates of overdiagnosis derived from older men should not be generalized to younger men. Prostate cancers diagnosed in younger men are more likely to cause harm in the long term, and it is uncertain whether all cases labeled as overdiagnosed are clinically insignificant. Contrary evidence suggests that screening with low PSA thresholds for biopsy in young patients detects tumors that fulfill the criteria for insignificant cancer in only 12% of patients (Krumholtz et al, 2002). Even among those that do, some tumors are multifocal or do not have a diploid complement of chromosomes. At present, no tumor marker or algorithm can identify indolent tumors with certainty.

Physicians discussing newly diagnosed prostate cancer with patients must decide on management based on the PSA level, the estimated tumor volume, and the Gleason score (up to one half of patients are upgraded on the basis of the radical prostatectomy specimen) (Pinthus et al, 2006; Suardi et al, 2008; Thaxton et al, 2010; Vellekoop et al, 2014) to select patients for immediate treatment or active surveillance. Repeated biopsies are always subject to sampling errors (Harnden et al, 2008) and may induce fibrosis in and around the prostate gland that could compromise subsequent nerve-sparing surgery, rendering it impossible to perform in more than half of patients (Barzell and Melamed, 2007), and may trigger inflammation leading to PSA fluctuations that are difficult to interpret.

Treatment is more likely to be successful if given earlier while the tumor is smaller and the prospects for potency-sparing surgery are greater. Deferred treatment is more appropriate for older patients with a limited life expectancy or comorbidities. Additional clinical and laboratory research are needed to define the parameters for safe use of active surveillance in younger men, including the appropriate selection criteria, follow-up procedures, and trigger points for intervention (Carter et al, 2003; Allaf and Carter, 2004; Wilt, 2008). It will also be necessary to determine the proportion of patients that would still have curable disease when they are treated at the time of objective disease progression. In many instances, active surveillance delays the treatment by only a few years; however, Freedland and colleagues reported that delays of more than 6 months conferred a 2.73-fold increased risk of progression in patients with low-risk prostate cancer (Freedland et al, 2006). Active surveillance frequently amounts to delayed treatment, and patients selected for active surveillance have cancers that are most curable with the fewest side effects. Some with curable disease would have surveillance until the opportunity for cure was lost, and it would be a mistake to treat patients only with incurable disease. For the present, patients who opt for active surveillance should be evaluated with DRE and PSA testing quarterly or semi-annually and should consider undergoing repeated prostate biopsy procedures yearly or biennially. In patients with a consistent PSA velocity exceeding 0.35 ng/mL/yr, there is a fivefold increased risk of prostate cancer death in the next two to three decades (Carter et al, 2006).

Although it is assumed that quality of life should be largely preserved with active surveillance, studies have demonstrated significant decrements in quality of life with time, including

waning erectile function, diminished urinary continence, and adverse psychological effects from living with untreated cancer (Hoffman et al, 2004). For example, in the Scandinavian study, men randomized to watchful waiting had a significantly worse quality of life than men randomized to radical prostatectomy (Johansson et al, 2009). This was especially true in men who received androgen deprivation therapy (ADT) (Johansson et al, 2009). A recent study reported that patients undergoing active surveillance and radical prostatectomy have a similar quality of life in most domains at 5 years of follow-up; however, at 6 to 8 years, active surveillance groups have more anxiety and depression (Bergman and Litwin, 2012).

If surveillance biopsy specimens show evidence of increased involvement by cancer, treatment should be instituted if the patient is otherwise healthy and has a 10-year or greater life expectancy. A rising PSA level alone is not an absolute indication for treatment in the active surveillance population; however, as stated earlier, PSA velocity risk count and [−2] proPSA are associated with risk for reclassification on active surveillance (Ross et al, 2010; Tosoian et al, 2012; Patel et al, 2014). Patients may change their mind about remaining on an active surveillance protocol; therefore the physician should review management options on follow-up visits.

In patients with a long life expectancy, there is a certain risk associated with active surveillance. Clearly, it can avoid or delay treatment for some patients, but there will inevitably be those who will miss their opportunity for cure and, tragically, ultimately progress to metastases and death from prostate cancer. Favorable outcomes have been reported in potential candidates for active surveillance treated with prompt nerve-sparing radical prostatectomy (Loeb et al, 2008).

The European prostate cancer screening trial has provided an unequivocally affirmative answer to half of the often-quoted aphorism of Willett Whitmore Jr. concerning prostate cancer, “Is cure possible when it is necessary?” The Scandinavian Prostate Cancer Study Group-4 trial of radical prostatectomy versus watchful waiting provides an affirmative answer to the second part, “Is cure necessary when it is possible?” The pendulum may swing too far toward active surveillance and then return more toward early active treatment.

KEY POINTS: CONSERVATIVE MANAGEMENT

- Prostate cancer treatment outcomes may be influenced by the malignant potential of the tumors as well as by the treatment used. Furthermore, outcome measurements are not necessarily comparable among different forms of therapy, confounding comparisons.
- Traditionally, deferred treatment has been reserved for men with a life expectancy of less than 10 years and a low-grade prostate cancer. Additional research is needed to define the parameters for safe use of active surveillance in younger men, including the appropriate selection criteria, follow-up procedures, and trigger points for intervention.
- A prospective, randomized clinical trial reported that patients with clinically localized prostate cancer managed with watchful waiting have significantly higher rates of local cancer progression, metastases, and death from prostate cancer than do those treated initially with radical prostatectomy. In addition, as discussed earlier, a prospective, randomized screening trial reported that prostate cancer screening with PSA and DRE reduces prostate cancer-specific mortality by 20% to 27% with early follow-up and up to 44% with longer follow-up. Because many of these patients were treated with radical prostatectomy, it may also be inferred to be evidence of the efficacy of radical prostatectomy for localized prostate cancer.

Radical Prostatectomy

Radical prostatectomy was the first treatment used for prostate cancer and has been performed for almost 150 years (Kuchler, 1866; Young, 1905). It is a technically formidable operation with considerable risks for side effects, and, as a result, simpler treatments have been sought for the treatment of early-stage disease. However, no treatment has supplanted radical prostatectomy, and it still remains the gold standard because of the realization that hormone therapy and chemotherapy are never curative, and not all cancer cells can be eradicated consistently by radiation or other physical forms of energy, even if the tumor is contained within the prostate capsule. Moreover, if the prostate gland remains in situ, it is possible for new prostate cancers to develop in the retained prostatic epithelium.

Innovations have led to the wider use of radical prostatectomy:

1. The development of the anatomic radical retropubic prostatectomy, which allows the dissection to be performed with good visualization and preservation of the cavernous nerves responsible for erectile function and preservation of the external sphincter muscle and yields urinary continence rates in excess of 90% (Walsh and Donker, 1982)
2. The development of extended ultrasound-guided biopsy regimens, performed with local anesthesia as office procedures (Arnold et al, 2001)
3. The widespread use of PSA testing, which has led to the majority of patients being diagnosed with clinically localized disease

In recent years, laparoscopic and robotic approaches have been developed for performing the operation.

The main advantage of radical prostatectomy is that it offers the possibility of cure with minimal collateral damage to surrounding tissues if it is skillfully performed (Han et al, 2001a; Hull et al, 2002). Furthermore, it provides more accurate tumor staging by pathologic examination of the surgical specimen. Also, treatment failure is more readily identified, potentially curative salvage radiotherapy can be undertaken, and the postoperative course is much smoother than in the past. Few patients require nonautologous blood transfusions. The hospital stay is usually 1 to 3 days, and operative mortality is rare in the modern era. Moreover, radical prostatectomy significantly reduces local tumor progression and distant metastases and improves cancer-specific and overall survival rates compared with watchful waiting (Bill-Axelson et al, 2008, 2014). Some patients with tumor recurrence after radical prostatectomy can be successfully treated with potentially curative postoperative radiotherapy (Stephenson et al, 2004b; Trock et al, 2008).

The potential disadvantages of radical prostatectomy are the necessary hospitalization and recovery period; a possibility of incomplete tumor resection, if the operation is not performed properly or if the tumor is not contained within the prostate gland; and a risk for erectile dysfunction and urinary incontinence. However, erectile dysfunction and rectal complications are less likely with nerve-sparing surgery than with radiotherapy, and good treatment options are available to treat both urinary incontinence and erectile dysfunction. Results reported from high-volume centers are more favorable than those from national surveys (Rabbani et al, 2000; Stanford et al, 2000; Kundu et al, 2004; Sanda et al, 2008; Pierorazio et al, 2013b).

In performing a radical prostatectomy, the surgeon must dissect in the proper tissue plane to remove the prostate from between the neurovascular bundles without permanently damaging the nerves or cutting into the prostate, or worse, leaving part of the prostate behind. Most prostate cancer patients have similar priorities. First they want to survive. Next, they want to remain continent. Third, they want to preserve their potency. These are their main priorities, but they want all three. This constellation of favorable outcomes is known as the "trifecta" (Eastham et al, 2008), and, understandably, patients want to achieve it as quickly and painlessly as possible. Often patients with newly diagnosed prostate cancer would like to avoid any treatment if possible or, after realizing that

treatment is necessary, seek the least burdensome option. This frequently leads to consideration of methods such as active surveillance, cryoablation, or high-frequency ultrasound ablation.

Surgical Approaches to Radical Prostatectomy

Perineal. Total perineal prostatectomy is an acceptable surgical treatment when performed by a surgeon familiar with this approach (Scolieri and Resnick, 2001). It is usually associated with less blood loss and a shorter operative time than the retropubic approach. The disadvantages are that it does not provide access for a pelvic lymph node dissection, there is a higher rate of rectal injury, and there is occasional postoperative fecal incontinence that does not occur commonly with other approaches (Bishoff et al, 1998). Also, it is more difficult to spare the cavernous nerves through the perineal approach.

Retropubic. The open retropubic approach was popularized because of surgeons' familiarity with the surgical anatomy; the lower risk for rectal injury and postoperative fecal incontinence; the wide exposure and ready access provided for pelvic lymphadenectomy; prostate excision with preservation of the neurovascular bundles; and the lower risk for cancer at the surgical margins.

Laparoscopic. The laparoscopic approach is the most daunting method of performing radical prostatectomy. It has been suggested that laparoscopic prostatectomy may be associated with less bleeding, better visualization, less postoperative pain, and shorter convalescence than the standard open approach. Laparoscopic prostatectomy can be performed through a transperitoneal or extraperitoneal approach, but the extraperitoneal approach poses logistical limitations, especially with the use of robotic assistance. The transperitoneal approach facilitates the lymphadenectomy but carries a higher risk of intestinal and vascular injury, urinary ascites, and postoperative ileus and intestinal obstruction.

Furthermore, laparoscopic prostatectomy is associated with a higher risk of severe complications. Hemostasis in the neurovascular bundles is difficult to achieve without applying thermal injury to the neurovascular bundles because of the relative difficulty in rapidly placing hemostatic sutures or applying hemostatic clips laparoscopically. Heat from a harmonic scalpel or electrocautery can irreversibly damage the cavernous nerves. Intraoperative blood loss is less with laparoscopic surgery. Rectal, ureteral, and vascular injuries and anastomotic leaks have also been more common with laparoscopic prostatectomy in some studies (Rassweiler et al, 2003).

A study comparing the results of laparoscopic and open radical prostatectomy revealed that although the laparoscopic approach was associated with less blood loss, of greater concern, it had higher rates of postoperative emergency room visits, readmissions to the hospital, and further surgery for complications (Touijer et al, 2008). Also, patients who underwent a laparoscopic radical prostatectomy were less likely to become continent than those treated with open prostatectomy.

When laparoscopic prostatectomy is performed by a skilled laparoscopic surgeon, reported continence and anastomotic stricture rates are comparable to those achieved with open surgery. It has been claimed that nerve sparing is equivalent or even better with laparoscopic surgery, but direct comparisons and validated results are lacking. The early reported rates of positive surgical margins have been higher with laparoscopic prostatectomy, and the adequacy of cancer control is as yet uncertain because of lack of long-term results (Touijer et al, 2009).

Robotic. Since the introduction of the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) in 2000, the majority of radical prostatectomies in the United States have been performed robotically. Robotic prostatectomy became popularized because of its greater technical ease for the surgeon, especially for tying sutures and performing the vesicourethral anastomosis, and lower blood loss, as in all laparoscopic approaches. It has been aggressively marketed as a less invasive, technologically more advanced method

of performing the operation with less pain and a quicker recovery. The availability of three-dimensional (3D) visualization and enhanced dexterity are its advantages over standard laparoscopic techniques. Robotic assistance has rendered minimally invasive radical prostatectomy technically feasible for many surgeons, whereas pure laparoscopic radical prostatectomy without robotic assistance is technically daunting and has a steep learning curve.

Earlier results were overall favorable (Smith, 2004; Webster et al, 2005; Menon et al, 2007, 2010). In more recent analyses of the impact of radical prostatectomy technique on surgical margin rates, cancer control, and outcomes, no superiority was seen between robotic and open radical prostatectomy for functional or oncologic outcomes (Pierorazio et al, 2013a; Silberstein et al, 2013). However, when a patient survey was used to assess functional outcomes in Medicare participants, robotic prostatectomy was associated with a trend toward more urinary incontinence and no difference in sexual function compared with open radical prostatectomy (Barry et al, 2012).

In terms of surgical incisions, usually six, albeit small, incisions are made in robotic surgery, and in most cases the procedure is performed transperitoneally; for open surgery, one incision 4 to 5 inches in length is made that does not enter into the peritoneal cavity. Comparative studies have shown that open prostatectomy has a similar recovery time and return to normal activity (Weizer et al, 2007; Wood et al, 2007). Meanwhile, robotic prostatectomy was associated with a significantly lower transfusion rate and shorter hospital stays compared with open radical prostatectomy (Tewari et al, 2012; Sammon et al, 2013) but a higher rate of incisional hernias (Carlsson et al, 2013).

Perhaps the most important consideration is that neither the laparoscopic nor the robotic approach has as long a track record of cancer control compared with the open approach (Touijer et al, 2009; Menon et al, 2010; Liss et al, 2012; Novara et al, 2012; Hruza et al, 2013). Even in an expert surgeon's hands, positive surgical margins were more frequent in robotic prostatectomy than open prostatectomy in the earlier studies (Williams et al, 2010; Novara et al, 2012). However, a recent meta-analysis reported lower positive surgical margin rates and complication rates in robotic prostatectomy compared with open radical retropubic prostatectomy and laparoscopic radical prostatectomy (Tewari et al, 2012), but these studies did not compare patients who were treated contemporaneously, and it is likely that patients treated with open prostatectomy had more advanced tumors.

A comparison of a sample of patients from the Medicare database who underwent minimally invasive or open prostatectomy in the earlier adoption period for robotic prostatectomy, from 2003 to 2005, revealed similar overall complication rates between minimally invasive and open prostatectomies; however, the men undergoing minimally invasive prostatectomy had more than a threefold higher rate of requiring salvage therapy for tumor recurrence within 6 months of surgery (Hu et al, 2008). In this study, the more experienced surgeons in minimally invasive radical prostatectomy had better results than less experienced surgeons; however, even the highest-volume minimally invasive surgeons had twice the rate of the patients requiring salvage treatment for cancer recurrence when compared with all surgeons performing open radical prostatectomy. Patients undergoing minimally invasive surgery also were 40% more likely to develop anastomotic strictures.

Schroek and colleagues compared patient satisfaction and regret after radical prostatectomy. Patients who underwent robotic prostatectomy were more than four times more likely to regret their decision (Schroek et al, 2008). The authors suggested that these patients were more likely to be regretful and dissatisfied because of the higher expectations for an "innovative" procedure. These results raise concerns that patients are being misled about the true risks and benefits of minimally invasive procedures to treat prostate cancer.

A population-based propensity-adjusted comparative assessment of robotic and open radical prostatectomy reported a lower rate for robotic prostatectomy in intermediate- and high-risk

patients and less use of additional cancer therapy within 6 months; however, patients undergoing open prostatectomy had less favorable tumor features (that might not be totally eliminated by propensity adjusting), and no data on the important end points of biochemical recurrence, metastases, and prostate cancer-specific mortality were reported (Hu et al, 2014).

Thus, the long-term outcome of cancer control is better documented for open prostatectomy. It is challenging to fairly compare functional outcomes among surgical techniques because of the inherent selection bias in these retrospective studies with different patient selection criteria and baseline comorbidities (Robertson et al, 2013; Yossepowitch et al, 2014). The recommendation for patients considering surgical treatment of their prostate cancer should be not to choose a technique but to choose an expert in a given technique. The importance of the surgeon's experience in reducing complications is well documented (Vickers et al, 2007, 2009; Klein et al, 2008; Abboudi et al, 2014; Thompson et al, 2014; Vickers, 2014).

Selection of Patients for Radical Prostatectomy

An ideal candidate for radical prostatectomy is healthy and free of comorbidities that might make the operation unacceptably risky. He should have a life expectancy of at least 10 years, and his tumor should be deemed to be biologically significant and completely resectable. The generally accepted upper age limit for radical prostatectomy is about 76 years. Older men are more likely to have metastases, and they have a greater risk for prostate cancer-specific death, despite higher death rates from competing causes (Scosyrev et al, 2012a).

Because imaging studies are not accurate for staging prostate cancer, preoperative clinical and pathologic parameters are often used to predict the pathologic stage and thus identify patients most likely to benefit from the operation (Partin et al, 1997, 2001; Makarov et al, 2007; Eifler et al, 2013). These parameters are frequently used in tables and nomograms designed to predict pathologic tumor stage or post-treatment recurrence-free survival probabilities (Kattan et al, 1998, 2000; Ross et al, 2001; Han et al, 2003). New methods of predicting the outcome after radical prostatectomy that incorporate cellular and biologic features to improve accuracy have been reported (Cooperberg et al, 2013; Karnes et al, 2013).

Patients with a low probability of resectable disease or a short life expectancy should not be advised to have surgery. Neoadjuvant hormone therapy does not enhance the resectability of prostate cancer and often increases the difficulty of performing nerve-sparing surgery (Soloway et al, 2002). Similarly, neoadjuvant chemotherapy rarely produces pathologic complete responses (Chi et al, 2008).

The surgeon should realistically counsel the patient on the nerve-sparing aspects of the operation. Nerve-sparing prostatectomy does not materially compromise cancer control in appropriately selected patients; however, it is inappropriate in men with advanced disease. The feasibility of performing nerve-sparing surgery is questionable when there is extensive cancer in the biopsy specimens, palpable extraprostatic tumor extension, serum PSA level above 10 ng/mL, biopsy Gleason score higher than 7, poor-quality erections preoperatively, current and future lack of a sexual relationship, or other medical conditions that may adversely affect erections (e.g., diabetes mellitus, hypertension, psychiatric diseases, neurologic diseases, or medications that produce erectile dysfunction).

Postoperative treatment of erectile dysfunction also should be discussed, including information on phosphodiesterase type 5 (PDE5) inhibitors, intraurethral and intracorporeal administration of vasodilators, vacuum erection devices, venous flow constrictors, and implantable penile prostheses. The discussion also should include the timing of the return of erections. The patient should be warned about the risk for development of Peyronie disease from injury to the penis during sexual activity without a rigid erection (Ciancio and Kim, 2000). He should also be informed

that early postoperative use of intracavernosal injection therapy with vasodilating drugs allows most patients to have normal erections (with arterial blood) shortly after the catheter is removed. This protects against the occurrence of atrophic changes in the penis and allows the resumption of sexual activity early in the postoperative period. If erectile function is a high priority for the patient, he should be reassured that erections almost always can be restored, regardless of whether nerve-sparing surgery could be performed.

The preoperative evaluation should consider the likelihood of success in achieving all goals of surgery and in determining whether the nerves can safely be spared. The surgeon should also discuss the possible need for and potential side effects of postoperative radiotherapy and/or hormone therapy if the final pathology specimen reveals adverse prognostic features or if the PSA does not reach undetectable levels.

Surgical Technique

Radical prostatectomy involves complete removal of the prostate gland and seminal vesicles and usually includes a modified pelvic lymph node dissection as well. The key steps in performing anastomotic nerve-sparing radical retropubic prostatectomy are as follows:

1. Pelvic lymphadenectomy
2. Opening of the endopelvic fascia and limited incision of the puboprostatic ligaments
3. Suture ligation and transection of Santorini dorsal venous complex
4. Dissection of the urethra at the apex of the prostate and transection of the urethra (sometimes the anastomotic sutures are placed at this point in the operation)
5. Dissection of the prostate from the neurovascular bundles
6. Securing and transection of the prostatic pedicles
7. Transection and reconstruction of the bladder neck
8. Dissection of the seminal vesicles and ampullary portions of the vasa deferentia
9. Performance of the vesicourethral anastomosis

The surgeon should strive for complete apposition of the bladder neck and the urethra, with a watertight, tension-free closure.

Pelvic lymphadenectomy is optional in patients at low risk for lymph node metastases. In fact, pelvic lymphadenectomy has been less frequently performed with robotic prostatectomy (Gandaglia et al, 2014). Patients who elect to undergo lymphadenectomy should decide in advance whether they wish to proceed with the prostatectomy if there are nodal metastases. If they do not wish to proceed, the excised lymph nodes are sent for frozen-section examination during the operation. Otherwise, intraoperative frozen-section analysis of pelvic lymph nodes is unnecessary. Some have argued that a more extensive pelvic lymphadenectomy yields better outcomes, but compelling evidence for this is lacking (Weight et al, 2008), and more extensive lymphadenectomy carries a greater risk for postoperative genital and lower extremity lymphedema and lymphocele (Bader et al, 2002; Allaf et al, 2004; Musch et al, 2008). Thromboembolic events and reinterventions are more common in patients with symptomatic lymphocele (Musch et al, 2008). It has been reported that pharmacologic venous thromboembolism prophylaxis reduces the risk of thromboemboli by 40%; however, prophylaxis is not used in many men who undergo radical prostatectomy (Weinberg et al, 2014).

The key to preserving urinary continence is to perform a meticulous dissection, avoiding injury to the external urinary sphincter. Preservation of the bladder neck is unnecessary to achieve good urinary continence. In patients with high-volume or high-grade tumors involving the base of the prostate, preservation of the bladder neck may risk positive surgical margins.

Meticulous dissection is also required to preserve the neurovascular bundles. In performing nerve-sparing surgery, the neurovascular bundles are identified at the apex of the prostate (the dissection can also be performed in an antegrade fashion beginning at the base), and the bundles are dissected free of the posterolateral surface of the prostate gland. Hemostatic sutures or clips may be used to control bleeding from the neurovascular

bundles. Use of electrocautery or a harmonic scalpel risks irreversible thermal injury to the neurovascular bundles.

The prostatic pedicles are suture ligated or hemoclipped and divided close to the gland, avoiding incision into the prostatic capsule. In performing the seminal vesicle dissection, care must be taken to avoid injury to the neurovascular bundles situated immediately lateral and posterior to them.

Postoperative Care

Patients should ambulate with assistance beginning on the afternoon or evening of surgery. The catheter may be removed 3 to 21 days after surgery, depending on the integrity and the amount of tension on the vesicourethral anastomosis. Removal of the catheter before 7 days is associated with a 15% to 20% risk of urinary retention.

After the catheter has been removed, Kegel exercises should be initiated. A protective pad is used until complete urinary control is achieved. The postoperative serum PSA level should be undetectable by 1 month after the operation, depending on the preoperative PSA level. Ultrasensitive PSA measurements frequently falsely classify patients as having tumor recurrence (Taylor et al, 2006).

Cancer Control

The principal objective of radical prostatectomy is to completely excise the cancer. Important cancer control end points are pathologically organ-confined disease with clear surgical margins, biochemical recurrence (detectable serum PSA), local progression, metastases, cancer-specific survival, and overall survival. As discussed earlier, depending on the Gleason score and the PSA doubling time, biochemical (PSA) evidence of recurrence usually precedes clinical metastases by a mean of about 8 years and cancer-specific mortality by about 13 years (Pound et al, 1999).

Nonprogression rates vary with clinical and pathologic risk factors. Independent clinical prognostic factors are tumor stage, Gleason score, preoperative PSA level, and treatment. Adverse prognostic features include non-organ-confined disease, lymphovascular space invasion, extracapsular tumor extension, positive surgical margins, seminal vesicle invasion, and lymph node metastases (Grossfeld et al, 2000; Shariat et al, 2004). In the PSA era, there has been a dramatic stage migration and improvement in prognostic features and treatment outcomes (Han et al, 2001b; Moul et al, 2002).

A rising serum PSA level is usually the earliest evidence of tumor recurrence after radical prostatectomy (Pound et al, 1999). Biochemical recurrence is frequently used as an intermediate end point for treatment outcomes; however, not all patients with biochemical recurrence ultimately develop metastases or die of prostate cancer. In rare instances with high-grade or neuroendocrine tumors that do not produce much PSA, there can be palpable evidence of recurrence despite an undetectable PSA level, indicating a role for DRE in monitoring of patients.

In hormone therapy-naïve men after radical prostatectomy, the median PSA at the time of a newly detected bone metastasis was 32 ng/mL, although a quarter of those metastases occurred at PSA levels of less than 10 ng/mL. Lower PSA at initial diagnosis of prostate cancer and higher Gleason score were correlated with metastasis development at lower PSA level (Loeb et al, 2010b).

The hazard of prostate cancer-specific recurrence continues to increase for at least 15 years after radical prostatectomy, and the risks for mortality may increase for 25 years or more (Shikanov and Eggener, 2011; Bill-Axelson et al, 2014). Therefore it is important to continue to monitor patients long after surgery (Popiolek et al, 2013).

Case selection and the duration and frequency of follow-up monitoring are also important determinants of postoperative outcomes. In Walsh's series of 4478 men who underwent anatomic radical retropubic prostatectomy from 1982 to 2011, without neoadjuvant or adjuvant therapy, during a median follow-up of 10 years

(range 1 to 29) the overall 25-year progression-free, metastasis-free, and cancer-specific survival rates were 68%, 84%, and 86%, respectively. There were significant differences in treatment outcomes between men treated in the pre-PSA and PSA eras. In each era, there were significant differences in progression-free, metastasis-free, and cancer-specific survival by risk groups (Mullins et al, 2012).

Radical prostatectomy also provides long-term cancer control in about half of highly selected men with high-risk or locally advanced disease (Freedland et al, 2007; Loeb et al, 2007; Ellis et al, 2013).

Urinary Continence

In general, urinary continence after radical retropubic prostatectomy is good and varies according to the experience and skill of the surgeon. For high-volume radical prostatectomy surgeons, more than 90% of men recover complete urinary continence. The return of urinary continence is associated with the patient's age: approximately 95% of men younger than 60 years can attain pad-free urinary continence after surgery; 85% of men older than 70 years regain continence. Relatively few require implantation of an artificial urinary sphincter or a sling procedure for stress urinary incontinence.

Erectile Function

Potency after radical prostatectomy is usually defined as the ability to maintain erections sufficiently rigid for penetration and sexual intercourse with or without the help of a PDE5 inhibitor. Most patients with intact libido and erections wish to maintain these functions. Others with poor-quality erections usually wish to have erections that at least offer some rigidity to provide sensory satisfaction for both sexual partners. The return of erectile function after radical prostatectomy correlates with the age of the patient, preoperative potency status, extent of nerve-sparing surgery, and era of surgery. In the most favorable candidates in whom preoperative potency is normal and bilateral nerve-sparing surgery can be performed, up to 95% in their 40s, 85% in their 50s, 75% in their 60s, and 50% in their 70s can attain recovery of erections sufficient for penetration and intercourse with or without the aid of a PDE5 inhibitor. However, in most instances, erections are not as good as they were preoperatively (Sivarajan et al, 2014).

Erections usually begin to return as partial erections 3 to 6 months after surgery and may continue to improve for up to 3 years or more (Burnett, 2005; Glickman et al, 2009). Patients should be encouraged to use erectile aids postoperatively, including PDE5 inhibitors, intraurethral suppositories, intracavernosal injections, or vacuum erection devices. Erection rehabilitation programs using intracavernosal injection therapy or PDE5 inhibitors might hasten the return of erections and increase the proportion of men who recover erections (Montorsi et al, 1997). However, it has been reported that "on-demand," rather than nightly, administration of PDE5 inhibitors was more efficacious in men with erectile dysfunction after bilateral nerve-sparing radical prostatectomy (Montorsi et al, 2008).

Complications

Anatomic nerve-sparing radical prostatectomy provides excellent cancer control with an acceptable complication rate in appropriately selected patients. The overall early complication rate after radical prostatectomy is less than 10% in experienced hands (Kundu et al, 2004). With a careful selection of patients and performance of necessary preoperative cardiovascular evaluation, perioperative mortality has been largely avoided (Mettlin et al, 1997; Kundu et al, 2004).

Early Complications. Early complications include hemorrhage; rectal, vascular, ureteral, and nerve injury; urinary leak or fistula; thromboembolic and cardiovascular events; urinary tract infection; lymphocele; and wound problems. It is advisable routinely to use support stockings and to ensure early ambulation. Prophylactic

anticoagulation and sequential compression devices are advisable in patients at high risk for thromboembolic complications. However, perioperative subcutaneous heparin injection may predispose to lymphoceles, and many surgeons reserve pharmacologic prophylaxis for high-risk patients (Orvieto et al, 2011).

Inadvertent injury to the obturator nerve can occur during the pelvic lymphadenectomy. When a tension-free primary nerve repair is not feasible, nerve grafting can be performed by a cutaneous or genitofemoral nerve graft. However, even without a nerve repair, conservative management with physical therapy can compensate for the deficit, and therefore many patients do not have a significant thigh adductor deficit after the injury (Kirdi et al, 2000).

Ureteral injury is a rare complication. A minor injury or ligation can be managed with removal of the ligature and ureteral stenting. Mobilization of the distal ureter and reimplantation should be performed for more severe injuries.

Although uncommon, a rectal injury can occur and be repaired primarily by a multiple-layer closure (Lepor et al, 2001; Roberts et al, 2010). However, a diverting colostomy should be considered in men with a large rectal defect, a history of pelvic radiotherapy, or long-term preoperative glucocorticoid therapy.

Late Complications. The most common late complications of radical prostatectomy are erectile dysfunction, urinary incontinence, inguinal hernia, incisional hernia with laparoscopic and robotic prostatectomy, and urethral stricture. Early rehabilitation measures, including Kegel exercises to increase the strength and the bulk of the external sphincter muscle and the use of a PDE5 inhibitor, vacuum erection device, and intraurethral or intracavernosal vasodilator, appear to be helpful in erectile function rehabilitation. Anastomotic or other urethral strictures should be managed initially with dilation, but internal incision and endoscopic injection of glucocorticoids may be required. For a long or persistent anastomotic stricture, a transurethral resection of the scar tissue cephalad to the external sphincter may be necessary. After the resection, an interval of catheter self-dilation of the anastomosis is usually required. Continued self-dilation or intermittent dilation by the urologist is required in difficult, persistent cases. Urethroplasty is rarely needed.

Management of Postoperative Biochemical Recurrence

Patients with detectable PSA (>0.1 ng/mL) after radical prostatectomy usually have persistent cancer, although some have only retained benign prostate tissue causing the PSA elevation. In the latter case, the serum PSA level increases slowly (Freedland et al, 2005). Of patients destined to have biochemical recurrence after radical prostatectomy, approximately 50% of recurrences appear within 3 years, 80% within 5 years, and 99% within 10 years. Rarely, recurrences appear more than 15 years after radical prostatectomy.

The PSA velocity or doubling time, the interval from surgery to biochemical recurrence, and the Gleason score usually reflect how rapidly the tumor is likely to progress (Freedland et al, 2005). In many patients, progression occurs relatively slowly, and only about one third actually develop metastases (Pound et al, 1999; Ward et al, 2004). Numerous studies have shown that patients with a rapidly rising PSA after biochemical recurrence have a high risk of progression to metastases and prostate cancer-specific mortality (Albertsen et al, 2004). In a study of men with a rising PSA after radical prostatectomy who did not receive immediate radiation therapy, the median time to metastases was 8 years after PSA elevation, but only 34% of men developed clinically apparent metastases (Pound et al, 1999).

If salvage radiotherapy is planned, it should be initiated before the PSA level rises much above 0.5 ng/mL (Cox et al, 1999). Patients most likely to have favorable responses to salvage radiotherapy are those with PSA recurrence long after surgery, a slowly rising PSA, low-grade tumor, and no seminal vesicle invasion or lymph node metastases. There is conflicting evidence concerning whether cancer at the surgical margins is a favorable or

unfavorable parameter for predicting response to postoperative radiation therapy, although reports suggest that patients with positive margins have a more favorable response rate. In one study, a multivariate analysis revealed that PSA doubling time, pathologic grade, and PSA at the time of salvage radiotherapy were independent predictors of clinical recurrence, whereas the interval from prostatectomy did not add independent predictive information (Ward et al, 2004).

With both adjuvant radiotherapy and salvage radiotherapy, the beneficial effects are controversial. Some patients fare well without it, whereas treatment in others who have distant metastases will fail despite the patient's having received it. Some patients with PSA recurrence are better managed with ADT than with salvage radiotherapy. Although many men with biochemical failure are treated with ADT, there are no data from prospective trials to address a possible progression-free or overall survival benefit. The most appropriate PSA level at which to institute hormone therapy is unknown. Because of the substantial side effects associated with long-term, continuous hormone therapy (decreased libido, impotence, hot flashes, osteopenia with increased fracture risk, metabolic alterations, and changes in mood), delayed or intermittent ADT is frequently used in patients who have biochemical recurrence, especially those with a slowly rising PSA level (Sharifi et al, 2005; Buchan and Goldenberg, 2010).

The Veterans Administration Cooperative Urological Research Group trials conducted in the 1960s did not show a survival benefit in patients with metastases treated with early ADT (Walsh et al, 2001). However, since then, other prospective, randomized clinical trials have suggested that early ADT is more effective than delayed ADT in patients with pelvic lymph node metastases (Messing et al, 1999) or those with locally advanced or asymptomatic metastatic disease (Immediate versus deferred treatment for advanced prostatic cancer, 1997). Nevertheless, it is uncertain whether these studies can be extrapolated to patients who have biochemical recurrence after primary treatment. A retrospective study reported no difference in early clinical outcome between early and delayed ADT in men with biochemical recurrence after radical prostatectomy (Moul et al, 2004). However, in high-risk patients, early ADT delayed the time to bone metastases.

High-dose bicalutamide administration has been reported to delay disease progression and yield overall survival results equivalent to those of treatment with orchiectomy among patients with PSA recurrence (Wirth et al, 2004). A possible advantage of this form of early hormone therapy is that it is associated with less risk for sexual dysfunction and osteoporosis than other forms of ADT. A disadvantage is a possible increased risk for cardiovascular complications and death associated with high-dose bicalutamide therapy.

Intermittent ADT is a reasonable alternative of providing early ADT while limiting the adverse side effects and expense of continuous ADT. There is accumulating evidence from prospective randomized trials that intermittent ADT is safe in patients without metastases and has survival outcomes comparable to those of continuous ADT (Carneiro and Da Silva, 1999; Lane et al, 2004; Calais da Silva et al, 2014; Buchan and Goldenberg, 2010; Crook et al, 2012; Sciarra et al, 2013).

Preoperative Androgen Deprivation Therapy. Preoperative ADT has been studied for tumor downstaging before radical prostatectomy in patients with locoregional prostate cancer. In general, the results have shown that although the rate of positive surgical margins is reduced, there is no benefit in terms of progression-free survival in the overall study population (Pal et al, 2014).

Although preoperative ADT might not uniformly be beneficial for localized disease, there might be a benefit in patients with high-risk disease. In a SWOG trial, patients with high-risk disease were randomized to receive either ADT alone or ADT with mitoxantrone. In patients receiving ADT alone in an *adjuvant* fashion in this study, biochemical recurrence-free survival was 92.5% at 5 years (Dorff et al, 2011). A Canadian Uro-Oncology Group trial also found improved biochemical progression-free survival with preoperative ADT in the highest-risk PSA group (PSA greater than 20 ng/mL) (Klotz et al, 2003). Similarly, in a retrospective institutional

study, among patients with high-risk disease, the time to biochemical recurrence was significantly longer in patients who had received preoperative ADT (Pal et al, 2014).

Several preoperative ADT trials have either been reported or are ongoing; these trials have assessed or are assessing the potential value of newly approved therapies for metastatic castration-resistant prostate cancer, such as abiraterone or enzalutamide, as preoperative ADT (Taplin et al, 2012).

Salvage Radical Prostatectomy

Radical prostatectomy can be performed in patients in whom other local treatments have failed (Pontes, 1994; Chen and Wood, 2003). However, the rate of complications is far higher, and the complications are more serious and difficult to manage (Stephenson et al, 2004a; Sanderson et al, 2006). Moreover, the prospects for long-term disease-free survival are more limited for salvage prostatectomy than for primary radical prostatectomy.

Most of the reported experience with salvage radical prostatectomy is from the pre-PSA era. Contemporary series of patients selected because of biochemical recurrence have lower morbidity and better cancer control rates (Stephenson et al, 2004a; Ward et al, 2005; Chade et al, 2011). Nevertheless, postoperative incontinence rates are as high as 44% and bladder neck contracture rates as high as 22% (Ward et al, 2005). The incontinence rate is even higher after brachytherapy, presumably because of the higher dose of radiation administered. Long-term progression-free survival rates after salvage prostatectomy in the absence of ADT have not been well documented.

KEY POINTS: RADICAL PROSTATECTOMY

- Radical prostatectomy was the first treatment used for prostate cancer, and it still remains the gold standard. An ideal candidate for radical prostatectomy is a healthy man with a life expectancy of at least 10 years. Preoperative clinical and pathologic parameters are often used to predict the pathologic stage and thus to identify patients most likely to benefit from the operation.
- A rising serum PSA level is usually the earliest evidence of tumor recurrence after radical prostatectomy and is frequently an intermediate end point for treatment outcomes. However, not all patients with biochemical recurrence ultimately develop metastases or die of prostate cancer.
- The most common late complications of radical prostatectomy are erectile dysfunction, urinary incontinence, hernia, and urethral stricture. The return of erectile function after surgery correlates with age of the patient, preoperative potency status, extent of nerve-sparing surgery, and era of surgery; the return of urinary continence is associated with the patient's age.
- The long-term outcome of cancer control is better documented for open prostatectomy.

Radiation Therapy

External beam radiotherapy most commonly involves the use of beams of gamma radiation, usually photons, directed at the prostate and surrounding tissues through multiple fields. To minimize radiation injury to the bladder and rectum, 3D conformal radiotherapy (3D-CRT), in which a computer alters the radiation beams to focus the radiation dose to the region of the prostate gland, was developed (Fraass et al, 1995). The most sophisticated form of 3D-CRT, intensity-modulated radiation therapy (IMRT), can provide localization of the radiation dose to geometrically complex fields (Zelevsky et al, 2006). Image-guided radiation therapy (IGRT) is a method in which imaging techniques are used to guide IMRT to the target area.

Heavy-particle therapy that uses beams of high-energy protons (Shipley et al, 1995; Rossi, 1999) or neutrons (Lawton et al, 1991; Russell et al, 1994) has also been used to treat patients with prostate cancer. Heavy-particle therapy is another form of 3D-CRT in which the radiation beam can be virtually stopped within the tissue, allowing high doses of radiation to be delivered to a localized region and smaller doses to surrounding normal tissues. However, proton beam therapy is extremely expensive, and limited long-term results have been reported (Shipley et al, 1995; Kagan and Schulz, 2010; Sheets et al, 2012; Gray and Efstathiou, 2013; Gray et al, 2013; Yu et al, 2013; Zietman, 2013; Hoppe et al, 2014; Yu et al, 2014). Although it has been reported that proton beam therapy has more gastrointestinal toxicity than IMRT (Sheets et al, 2012), a Medicare analysis of proton beam therapy versus IMRT reported no differences in genitourinary or gastrointestinal toxicity by 24 months after treatment (Yu et al, 2013, 2014).

A possible disadvantage of extreme conformal therapy with IMRT and heavy particles is that they can be too narrowly targeted, so that movement of the prostate caused by differences in rectal or bladder filling could result in geographic misses of the tumor, especially in the important posterior peripheral region of the prostate.

Radiation therapy has been extensively studied for localized prostate cancer. The outcomes of radiation therapy corrected for anatomic disease extent and other prognostic factors have been reported to be comparable to those of radical prostatectomy; however, this is misleading because the end points for determining treatment success or failure are different for radiotherapy and surgery (Gretzer et al, 2002).

Radiation Dose and Field of Treatment

There is evidence from prospective randomized trials that dose escalation and 3D definition improve results considerably (Pollack et al, 2002; Spratt et al, 2014). Currently, doses of 76 to 80 Gy or more have been shown to improve cancer control (Pollack et al, 2000; Dearnaley et al, 2007; Zelefsky et al, 2011). Low-risk patients are now frequently treated with 70 to 72 Gy, intermediate-risk patients with 75 to 76 Gy, and high-risk patients with 80 Gy or more. Doses above 75 Gy are now considered to be indicated; however, doses above 80 Gy have not been demonstrated to be beneficial.

Although the prostate itself can tolerate high doses of radiation, the rectal toxicity limits the dose that can be given in brachytherapy. Image guidance for better target definition is crucial for dose escalation, and high radiation doses require protection of normal tissues. IMRT produces steep dose gradients in which the gradient between 100% and 50% of dose can be as little as 1 to 1.5 cm. Radiation dose escalation requires precision in target definition and a high degree of accuracy in the daily placement of the radiation dose. IMRT offers a safer means of dose escalation (Michalski et al, 2013).

CT imaging is considered the standard imaging modality for 3D-CRT and 3D-IMRT, but CT is less precise than MRI. Therefore, larger margins are required to accurately ensure that the entire prostate gland receives the daily radiation dose. When CT imaging uses only the bone landmarks to localize the prostate gland, the daily radiation treatments might be directed inconsistently, and the rectum might receive increased doses of radiation (Karamanolis et al, 2009).

Radiation Side Effects

The main adverse side effects of radiation therapy are related to injury to the microvasculature of the bladder, rectum, striated sphincter muscle, and urethra. However, urinary incontinence or radiation-induced complications requiring surgical correction are uncommon. Approximately one third of patients experience acute symptoms of proctitis or cystitis during the course of radiotherapy, usually after the dose exceeds 50 Gy. In the great major-

ity, symptoms subside after the completion of therapy. About 5% to 10% have permanent symptoms, such as irritable bowel syndrome and intermittent rectal bleeding or bladder irritability and intermittent gross hematuria (Nam et al, 2014). In comparing morbidities after different radiation therapies, IMRT was associated with reduced gastrointestinal morbidity compared with 3D-CRT and proton therapy (Sheets et al, 2012). In some patients, chronic symptoms develop years after treatment. Some patients require laser cauterization or argon plasma coagulation of radiation-induced telangiectasia for bleeding from the bladder or the rectum (Artibani et al, 2007; Karamanolis et al, 2009). External beam radiotherapy causes more rectal toxicity and less urinary toxicity than brachytherapy (Ferrer et al, 2013).

A prior transurethral resection of the prostate is a relative contraindication to brachytherapy and external beam radiation therapy because the prostate does not hold the seeds well, and radiation after transurethral resection of the prostate is associated with an increased risk of urethral stricture (Devisetty et al, 2010). The presence of severe obstructive urinary symptoms is also a relative contraindication because of the risk of acute urinary retention, which is an even greater risk in patients treated with brachytherapy. Another relative contraindication is inflammatory bowel disease. On the other hand, radiotherapy can gradually relieve obstructive urinary symptoms in men with urinary outflow obstructive symptoms (Malik et al, 2011).

Approximately one half of patients develop erectile dysfunction after radiotherapy for prostate cancer. This is caused by injury to the vasculature of the cavernous nerves and to the corpora cavernosa of the penis, usually beginning about 1 year after the completion of treatment. Younger patients with good baseline erectile function are more likely to retain adequate erections. PDE5 inhibitors are useful in ameliorating the erectile dysfunction associated with radiotherapy (Merrick et al, 1999; Zelefsky et al, 2014). Lower doses of radiation to the penile bulb have been investigated as a means of minimizing radiation-induced erectile dysfunction (Roach et al, 2004). The use of adjuvant ADT also adversely affects erectile function. A study evaluating erectile function in men treated with radiotherapy reported that post-treatment erections were much worse if there was preexisting difficulty or if neoadjuvant ADT was used. However, in one study, a large percentage of patients treated with radiotherapy had never tried erectile dysfunction treatments (Alemozaffar et al, 2011).

Combined External Beam Radiation Therapy and Androgen Deprivation Therapy for Locally Advanced Prostate Cancer

Randomized clinical trials have demonstrated that patients with an intermediate- or high-risk tumor benefit from ADT in conjunction with radiotherapy, whereas those with lower-risk tumors do not. For example, Bolla and colleagues reported that a 3-year course of adjuvant hormone therapy started concurrently with external beam radiation improved local tumor control and survival in patients with locally advanced prostate cancer without significant differences in cardiovascular mortality (Bolla et al, 2002, 2010). Hanks and associates explored the optimal duration of ADT after radiation therapy (Hanks et al, 2003). They showed that 28 months of ADT before, during, and after radiation therapy compared with 4 months of ADT before and during radiation therapy provided significant improvement in all clinical end points except for overall survival (Hanks et al, 2003). However, an overall survival benefit of a longer course of hormone therapy was observed in patients with Gleason grade 8 to 10 disease.

In men with clinical stage T2b to 4N0 disease treated with radiation therapy, ADT of 3 or 6 months' duration improved external beam radiation therapy treatment outcomes (Denham et al, 2011). Concern has been expressed about the possible cardiovascular risks of ADT, particularly the risk of fatal myocardial infarction. Although some studies have reported an increased rate of cardiovascular deaths (D'Amico et al, 2007; Tsai et al, 2007), two prospective trials revealed that although ADT increased the risk of diabetes mellitus,

heart disease, and myocardial infarction, there was no detectable increase in the risk of cardiovascular mortality (Van der Kwast et al, 2007; Efsthathiou et al, 2008, 2009). In addition, a meta-analysis of randomized trials in men with unfavorable nonmetastatic prostate cancer showed that ADT did not increase the risk of cardiovascular death (Nguyen et al, 2011).

In a randomized trial, the combination of radiotherapy plus 6 months of ADT provided inferior survival compared with radiotherapy plus 3 years of ADT in the treatment of clinically localized prostate cancer (Bolla et al, 2009). In a post hoc analysis of three phase III studies of ADT therapy for intermediate-risk cancer treated with radiotherapy with a median follow-up of 10.9 years, 6 months of ADT improved prostate cancer–specific mortality compared with 3 to 4 months in patients with Gleason score 7 prostate cancer (D’Amico et al, 2011). Thus, longer courses of ADT are, in general, recommended for patients with higher-risk disease (Roach, 2014).

Radiation Therapy for Localized Prostate Cancer

No randomized trial has exclusively studied the additional benefit of ADT in the high-risk patients receiving radiotherapy for *localized* prostate cancer. However, on the basis of the randomized trials involving locally advanced disease, long-term concurrent ADT is recommended for unfavorable intermediate-risk, localized high-risk, and locally advanced prostate cancer (Roach, 2014).

In a retrospective cohort study, D’Amico and coworkers (2000) showed that 6 months of ADT (beginning 2 months before and continuing during and after radiation therapy) improved the PSA outcomes in intermediate- and high-risk patients but not in low-risk patients. In a subsequent randomized trial, D’Amico and colleagues (2008) confirmed that 6 months of ADT improved outcomes, mostly in the intermediate-risk patients; ADT was associated with an earlier onset of fatal myocardial infarcts in this study (D’Amico et al, 2007).

On the basis of these studies, **long-term ADT is usually recommended along with external beam radiotherapy in patients with locally advanced disease or localized high-risk disease. In patients with intermediate-risk, localized disease, short-term (6-month) ADT is usually recommended.**

End Points for Treatment Success or Failure

Evaluation of the outcomes of radiotherapy is complicated because cancer cells are not killed immediately after exposure to ionizing radiation. Rather, they sustain lethal DNA damage, but do not die until their next attempt to enter into cell division. Thus, the PSA level gradually decreases for up to 2 to 3 years after the completion of radiotherapy. Accordingly, the PSA level is usually monitored at 6-month intervals until it reaches a nadir. In patients treated with external beam radiotherapy, the prostate gland is not completely ablated and the remaining prostate epithelium continues to produce PSA. Also, inflammation in the prostate gland can produce transient PSA elevations, called a PSA “bounce” (Critz et al, 2003). PSA bounce occurs in about 20% of patients, usually during the first 2 years after treatment, and is more common with brachytherapy (Thompson et al, 2010). Patients with a PSA bounce are more likely to have biochemical failure, and a PSA bounce of greater than 1.4 ng/mL has been associated with biochemical failure, metastases, and prostate cancer death (Feigenberg et al, 2006). Adequate follow-up is necessary to discern whether a PSA increase indicates failure (Thompson et al, 2010).

The biochemical end point used to determine treatment success after external beam radiation therapy is controversial. Until recently, the most frequently used definition was the American Society for Therapeutic Radiology and Oncology (ASTRO) definition (Cox et al, 1999). It required three consecutive PSA increases measured 6 months apart and backdated the time of cancer progression to halfway between the PSA nadir and the first rising PSA level. Thus, it usually took years to determine whether tumor progression had occurred. Without long-term follow-up, the ASTRO definition yielded progression-free survival estimates that appeared 10% to

20% better than they actually were because it takes time for the PSA level to reach a nadir and even more time for three consecutive PSA increases to occur. Moreover, in clinical series there are always more patients with shorter follow-up than with longer follow-up. Thus, backdating of the time of the recurrence moves the time of the recurrence event to a point in the series where the denominator is larger, and therefore the impact of the recurrence on the survival curve is diminished.

The Phoenix definition has replaced the ASTRO definition (Roach et al, 2006). It eliminates backdating but requires the PSA level to rise by 2 ng/mL before treatment failure is declared. Thus the time to recurrence is further prolonged after the PSA level begins to rise, and often it takes a considerably longer time for the PSA level to increase by 2 ng/mL. In some patients, adjuvant ADT may be initiated before the PSA rises to 2 ng/mL. In practice, the Phoenix definition can yield results that are even more favorable than those obtained with the ASTRO definition. Accordingly, it is not possible to make fair comparisons between radical prostatectomy and radiotherapy by use of these outcome measurements (Hoffman et al, 2013).

Treatment Results of External Beam Radiotherapy

With conventional external beam radiotherapy, the 10-year cancer cure rates for patients with clinically localized prostate cancer were approximately 50% (Zietman et al, 2004). Better results have been achieved with 3D-CRT, IMRT, and dose escalation. However, with dose escalation, there is not only a higher chance for cure, but also a higher risk of rectal morbidity (Kuban et al, 2008). As discussed earlier, high-risk patients are frequently treated with 2 to 3 years of ADT after radiotherapy (Bolla et al, 1997; Pilepich et al, 1997). With this regimen, the 5-year progression-free probabilities have been reported to be 70% to 85% (Bolla et al, 1997; Kuban et al, 2008). There are limited data concerning the durable and favorable responses to radiation therapy, especially in young patients. A substantial proportion of patients who are unsuccessfully treated with radiotherapy have tumor recurrence within the radiation field, usually in the central part of the tumor. A decrease in the PSA to 0.5 ng/mL or less after radiotherapy (with or without ADT) is associated with improved prostate cancer–specific mortality rate (D’Amico et al, 2012).

Long-term outcomes support the use of dose-escalated radiotherapy to improve biochemical progression-free survival and distant metastasis rates. A retrospective study of patients with stage T1 to T3 disease treated with 3D-CRT or IMRT in doses of 64 to 86 Gy with or without ADT for a median of 6 months and a median follow-up of 8 years reported that the radiation dose and the use of ADT were both associated with a better biochemical-free survival rate and fewer metastases. However, there was a substantial decrease in PSA control between 5 and 10 or more years of follow-up (Zelevsky et al, 2011). Another long-term phase III study reported that combining ADT with radiotherapy improved the outcomes for intermediate- to high-risk prostate cancer and further supported a role for using higher radiation doses (Denham et al, 2011).

It has been questioned whether the benefits of radiation plus ADT are superior to ADT alone for locally advanced disease. A Scandinavian trial comparing ADT alone with ADT plus radiation in patients with locally advanced prostate cancer revealed that ADT plus radiotherapy halved the 10-year prostate cancer–specific mortality and substantially decreased overall mortality with fully acceptable risk of side effects compared with ADT alone (Widmark et al, 2009). This conclusion was further supported by a phase III study with a median follow-up of 6 years in which the addition of radiotherapy to ADT increased overall survival with little added morbidity. The authors concluded that **men with locally advanced, nonmetastatic disease should not receive ADT alone; rather, ADT combined with radiotherapy should be the new standard** (Warde et al, 2011).

In high-risk patients, external beam radiotherapy has also been combined with brachytherapy (Spratt et al, 2014). The

brachytherapy is usually given first, so that the external beam therapy can be discontinued if the patient begins to experience toxicity (Ragde et al, 1997; Critz et al, 1998; Ragde et al, 1998).

Stereotactic Body Radiation Therapy (CyberKnife)

Stereotactic body radiation therapy (SBRT) involves a linear accelerator mounted on a robotic arm, giving large doses of radiation in a small number of fractions (hypofractionation). Giving larger doses of daily radiotherapy may improve cure rates without increasing toxicity of treatment (Arcangeli et al, 2010).

Limited results have been published in a small number of patients with low-risk disease. These results provide some evidence of short- and intermediate-term safety and evidence of PSA decline, but evidence of long-term safety and efficacy is lacking (King et al, 2009, 2013).

Several phase I studies have reported that with early follow-up SBRT appears to be well tolerated. A phase I multi-institutional study of 5-fraction SBRT for low-risk prostate cancer, using IMRT to deliver 37 Gy/5 fractions with a median follow-up of 44 months, has shown acceptable toxicity rates so far, but further follow-up is needed. SBRT is less costly than standard IMRT (McBride et al, 2012). Another phase I study of men with stage T2b disease or lower, with treatments of 45, 47.5, and 50 Gy in 5 fractions and IGRT with an enema and a rectal balloon to minimize rectal motion, showed minimal toxicity with a median follow-up of 30 months (Boike et al, 2011).

Although initial reports indicated similar treatment efficacy, no long-term follow-up is available to draw conclusions about disease control or late toxicity (Buyyounouski et al, 2010; McBride et al, 2012). A recent report of quality of life after up to 5 years has somewhat allayed concerns over late toxicity (King et al, 2013). Therefore, more research is needed to put hypofractionated radiotherapy on a sound scientific basis (Kupelian et al, 2007; King et al, 2012).

Heavy-Particle Radiotherapy

High-dose proton or neutron beam therapy has been advocated as a more effective method of CRT, but there is no convincing evidence that treatment results are superior to those achieved with photons (Zietman et al, 2005; Martinez et al, 2011; Gray et al, 2013; Zietman, 2013; Hoppe et al, 2014). The gastrointestinal, genitourinary and sexual quality-of-life domains after proton beam therapy have been reported to be similar up to 2 years after therapy (Hoppe et al, 2014).

Brachytherapy

With brachytherapy, radioactive sources (seeds or needles) are implanted directly into the prostate gland, and sometimes into the surrounding tissues, to deliver a high dose of radiation to the tumor while sparing, to the extent possible, the bladder and the rectum. Modern brachytherapy for prostate cancer was originally unsuccessful because freehand implantation of the seeds provided a poor radiation dose distribution; however, newer external template-based techniques provide more uniform implantation patterns.

Brachytherapy has become popular for treatment of patients with clinically localized prostate cancer. It can be performed under general or regional anesthesia. The most commonly used permanent implants are iodine-125 (^{125}I), palladium-103 (^{103}Pd), or cesium-131 (^{131}Cs) seeds. Theoretically, palladium offers a higher radiation dose rate than would be expected to be advantageous for treatment of poorly differentiated tumors that have a shorter cell cycle. However, in practice, no significant advantage has been demonstrated for the use of palladium. Although high-dose rate (HDR) temporary implantation with iridium-192 wires has been used for more aggressive tumors, logistical considerations make it time-consuming, inconvenient, and less practical in many clinical settings.

Brachytherapy Radiation Dose and Fields

There is no preferred isotope (^{125}I , ^{103}Pd , or ^{131}Cs) for brachytherapy and no consensus on the use of supplemental external beam radiotherapy or ADT. Postimplant dosimetry is mandatory, including prescribed dose (D90 or V100 and the normal tissue dose). Brachytherapy is also operator dependent, and quality assurance is vital (Rosenthal et al, 2011).

After the implant has been completed, a post-treatment CT scan is routinely obtained to check the postimplant dosimetry. Dosimetry can be adversely affected by poor implantation or migration of the seeds after implantation. The radiation doses delivered to the prostate are approximately 145 Gy for iodine and 125 Gy for palladium, which are substantially higher than those for external beam radiotherapy. As with external beam radiotherapy, radiation dose is important with brachytherapy (Stone et al, 2007a; Kao et al, 2008). Biochemical recurrence is associated with dosimetry. HDR brachytherapy as a monotherapy has been reported to achieve results similar to external beam radiation in intermediate-risk prostate cancer (Rogers et al, 2012; Yamada et al, 2012).

Direct comparisons of radiation doses between external beam radiotherapy and brachytherapy are not valid; because of the much higher doses of radiation delivered, brachytherapy causes more ablation of the prostate gland. Thus in many patients treated with brachytherapy, post-treatment PSA levels decrease into the undetectable range. Despite this, brachytherapy is seldom used for the treatment of high-volume, high-risk prostate cancers, because IMRT is the preferred method for treatment of aggressive tumors (Spratt et al, 2014).

In patients who have an enlarged prostate gland, it can be technically challenging to implant the entire prostate volume, especially anteriorly. Accordingly, patients are often treated with ADT to shrink the prostate before brachytherapy is performed. Long-term ADT confounds assessment of the response to brachytherapy because it delays PSA rises that would signal tumor persistence or recurrence.

Transrectal ultrasound-guided brachytherapy is the standard approach. MRI is currently being investigated for use in preplanning and postplanning dosimetry with urethral sparing. MRI-CT fusion scans have also been used for this purpose (Bowes et al, 2013).

Results of Brachytherapy

Excellent short-term cancer control rates have been reported with brachytherapy. With the ASTRO failure criteria, 5- and 7-year progression-free survival estimates of 85% and 80%, respectively, have been reported for groups of largely low-risk patients (Ragde et al, 2001). Permanent brachytherapy alone also has been reported to be effective for intermediate-risk patients (Zelevsky et al, 2007). Low-dose rate brachytherapy as monotherapy for low- or intermediate-risk prostate cancer (most patients also receiving ADT) with a median dose of 151 Gy has been reported to yield excellent cancer control ($\leq 6\%$ risk of PSA recurrence at 10 years) (Morris et al, 2013).

External beam radiotherapy combined with permanent-source brachytherapy has been reported to have an efficacy similar to high-dose external beam radiotherapy alone, with possibly increased urinary toxicity (Lee et al, 2007). Dose escalation with brachytherapy boost has been reported to improve disease control and survival (Shilkrut et al, 2013).

A retrospective study reported that HDR monotherapy is safe and effective (median follow-up only 35 months) for intermediate-risk prostate cancer and may be superior to external beam radiotherapy with or without ADT (Rogers et al, 2012). This study adds to the existing literature in support of dose escalation (with HDR brachytherapy) (Martinez et al, 2011).

Side Effects of Brachytherapy

Urinary symptoms are more common after brachytherapy than after external beam radiotherapy, especially in patients with

prostatic hyperplasia. To avoid these problems, α -adrenergic blockers and ADT are usually administered before treatment. Urinary retention occurs in up to 22% of patients. Approximately 10% of patients require transurethral resection of the prostate after brachytherapy. If an aggressive transurethral resection of the prostate is performed, there is a high rate of incontinence, occurring in 20% to 40% of patients. However, a more conservative, "channel" transurethral resection or laser prostatectomy can usually restore voiding function while preserving continence. Preservation of erectile function has been reported in 62% to 86% of patients treated with brachytherapy alone. Impotence rates are higher when brachytherapy is combined with external beam radiotherapy. Furthermore, neoadjuvant ADT frequently used before brachytherapy adversely affects postoperative erectile function. PDE5 inhibitors may be helpful in restoring erections.

Proctitis and rectal injury are less common with brachytherapy than with external beam therapy, but erectile dysfunction occurs more commonly with brachytherapy than with external beam radiation. Other complications associated with brachytherapy include seed migration and rectourethral fistula (Theodorescu et al, 2000; Di Muzio et al, 2003).

Postoperative Radiotherapy as Treatment of Patients with Adverse Pathology

The management of patients with positive surgical margins after radical prostatectomy has recently been reviewed (Valicenti et al, 2013; Yossepowitch et al, 2014). Patients with extracapsular tumor extension, seminal vesicle invasion, or positive surgical margins might have retained cancer cells in the bed of the prostate, and postoperative radiotherapy may eradicate these cells. Radiotherapy administered proactively shortly after surgery (after urinary continence has been attained) in patients with undetectable PSA levels is called *adjuvant* radiotherapy. In contrast, radiotherapy given selectively to men with detectable postoperative PSA levels is called *salvage* radiotherapy. A theoretic advantage of adjuvant radiotherapy is that it is more likely to be successful when the tumor burden is the smallest; however, because PSA is a highly sensitive test, little is lost by delaying with careful monitoring, and most patients whose PSA will never rise will be able to avoid unnecessary postoperative radiotherapy. There is controversy about whether adjuvant or early salvage treatment is preferred as well as about the optimal radiation dose and additional use of ADT (Briganti et al, 2012).

Adjuvant Radiotherapy

There is no controversy regarding whether patients with adverse findings in the radical prostatectomy specimen benefit from adjuvant radiotherapy. However, because there is no convincing survival evidence, the role of adjuvant radiotherapy is debatable when compared with early salvage radiotherapy (Bolla et al, 2012). Adjuvant radiotherapy is usually administered to the bed of the prostate gland in doses in the range of 64 Gy to 72 Gy. It is advisable to wait at least 3 to 4 months after surgery to allow complete wound healing and return of urinary continence. Radiation to the whole pelvis is usually discouraged because of the higher risk for bowel complications (Joo et al, 2013). With adjuvant therapy, the radiation dose is less than for salvage radiotherapy, and there is less need for ADT.

Adjuvant radiotherapy is most likely to benefit patients with positive surgical margins or extracapsular tumor extension without seminal vesicle invasion or lymph node involvement. However, not all patients with extracapsular extension or positive margins have tumor recurrence without adjuvant radiotherapy, and many with highly adverse findings will have treatment failure with distant metastases despite adjuvant radiotherapy. Nevertheless, it is possible that some patients with seminal vesicle invasion or lymph node metastases might benefit from adjuvant radiotherapy with ADT (Cozzarini et al, 2004; Abdollah et al, 2014). There

is level 1 evidence demonstrating the benefits of adjuvant radiotherapy that makes a strong case for discussing it with all patients with adverse pathology findings on the radical prostatectomy specimen.

The SWOG 8794, European Organisation for Research and Treatment of Cancer (EORTC) 20911, and German Cancer Society (ARO 96-02) studies show that **adjuvant radiotherapy reduces the risk of biochemical recurrence by 50% to 60%**. An update of SWOG 8794 (but not EORTC 20911) showed that this benefit extended to a significantly lower risk of metastases and longer overall survival (Bolla et al, 2005; Thompson et al, 2009). The long-term update of EORTC 22911 for patients with pT3 disease or positive margins showed no benefit with regard to distant metastases or overall survival; however, there was a reduction of relapse (Bolla et al, 2012). These latter benefits have been questioned because the cause of death was not ascertained and the surveillance patients had twice as many highly aggressive cancers. Patients with positive margins, including those with high-grade cancers and seminal vesicle invasion, appeared to benefit the most (Van der Kwast et al, 2007).

The EORTC trial showed benefit not only in patients with positive surgical margins but also in those with extracapsular tumor extension and seminal vesicle invasion (Bolla et al, 2005). In the SWOG trial there was a lesser improvement but still a significant benefit for the subset with seminal vesicle involvement (Swanson et al, 2008).

Most patients with focally positive surgical margins, with or without extraprostatic tumor extension, are cured by radical prostatectomy (Eggerer et al, 2011; Spahn and Joniau, 2013). Because adjuvant radiotherapy can be associated with complications, if every patient with adverse pathology were treated, many would be exposed to these side effects unnecessarily. Also, not every patient whose disease progresses is destined to develop metastases and die of prostate cancer (Boorjian et al, 2010; Eggerer et al, 2011; Mauermann et al, 2013), as is reflected by the EORTC 22911 trials showing a progression benefit but not a survival benefit (Bolla et al, 2012). In addition, there is accumulating retrospective evidence that early salvage radiotherapy yields results that are comparable to adjuvant therapy while avoiding treatment in a substantial proportion of patients (Stephenson et al, 2007; Trock et al, 2008; Briganti et al, 2012). Thus the clinical trials of adjuvant radiotherapy have paved the way for early salvage radiotherapy.

Salvage Radiotherapy

Depending on the risk for tumor recurrence, some patients do not opt for adjuvant radiotherapy but rather choose to monitor their PSA levels and avoid further treatment unless there is convincing PSA evidence of tumor progression. Giving salvage radiotherapy early with a very low PSA could be an acceptable alternative to adjuvant radiotherapy (Briganti et al, 2012; King, 2012; Pfister et al, 2014). However, the results of a randomized trial that compared adjuvant radiotherapy with early salvage radiotherapy have not yet been reported.

A multi-institutional retrospective analysis reported that 50% of patients had disease progression at a median follow-up of 45 months after salvage radiotherapy, 10% developed metastases, and 4% died of prostate cancer. The actuarial 4-year progression-free probability was about 45%. In this series, predictors of progression were Gleason grade of 8 or higher, preradiation PSA level above 2 ng/mL, negative surgical margins, and PSA doubling time of 10 months or less (Stephenson et al, 2004b). However, in this series, salvage radiation was sometimes not instituted early in the course of tumor recurrence, as indicated by the relatively high PSA levels.

A retrospective study of men with PSA failure after radical prostatectomy that was unique in that patients received no treatment, salvage radiation therapy, or salvage radiation therapy with ADT reported that **salvage radiotherapy was associated with a threefold reduction in prostate cancer mortality**, and although the addition of ADT provided no additional decrease in the risk for mortality,

the patients who received ADT had higher-risk disease (Trock et al, 2008). Therefore, ADT probably provided additional benefit for these high-risk patients. The benefit was strongest in those with the shortest PSA doubling times, but it is possible that with longer follow-up, a significant benefit also might become apparent in patients with less aggressive tumors (Cotter et al, 2011). **This study has changed the previous dogma that patients with the most aggressive tumors (i.e., rapid PSA recurrence, seminal vesicle invasion, rapid PSA doubling time) do not benefit from salvage radiotherapy.**

A long-term randomized trial reported that whole pelvis radiotherapy improves progression-free survival in men with greater than a 15% risk of pelvic node involvement (Lawton et al, 2007). A matched-pair analysis of patients with lymph node metastases treated with ADT plus radiotherapy versus ADT alone with a median follow-up of 95 months revealed a better 10-year cancer-specific and overall survival with combined therapy. This compels consideration for the role for combined modality therapy in patients with lymph node metastases (Briganti et al, 2011; Kaidar-Person et al, 2013). However, the preponderance of evidence suggests that **pelvic radiotherapy increases toxicity but has no proven effect on survival** (Lawton et al, 2007; Pommier et al, 2007).

Approximately 50% of patients will have a durable response to salvage radiotherapy, but in the absence of clinical trial data, it is not possible to determine the extent to which it reduces clinical tumor recurrence, metastases, and prostate cancer-specific mortality. The location and number of positive margins may not be associated with the outcome after salvage radiotherapy. In general, Gleason grade 8 to 10 is associated with a poorer durable response rate (Bastide et al, 2010; Karlin et al, 2013).

The results of retrospective matched control analyses comparing adjuvant and salvage radiotherapy are conflicting. Several studies reported that adjuvant radiotherapy was superior because the biochemical progression rates were lower than after salvage therapy (Trabulsi et al, 2008; Budiharto et al, 2010; Ost et al, 2011). However, in these studies, a relatively high PSA cutoff triggered salvage therapy. In contrast, in a propensity-matched analysis of men with extraprostatic tumor extension with or without positive margins but with negative lymph nodes in which adjuvant therapy was given within 6 months after surgery and a PSA trigger of 0.5 ng/mL was used to trigger salvage therapy, no significant difference in biochemical recurrence-free rates was observed between adjuvant and salvage radiotherapy in patients with positive margins (Briganti et al, 2012).

Based on a literature review, improved 5-year biochemical progression-free survival rates were observed for patients who received early salvage radiotherapy (PSA ≤ 0.5 ng/mL) compared with patients treated with salvage radiotherapy with a preradiotherapy PSA value above 0.5 ng/mL. Whether the routine application of adjuvant radiotherapy in patients with initially undetectable PSA levels will be associated with demonstrable clinical benefit awaits the results of ongoing prospective trials.

Two prospective phase III randomized trials have been initiated to compare adjuvant versus early salvage therapy in high-risk patients (the Radiotherapy and Androgen Deprivation in Combination after Local Surgery [RADICALS] trial, conducted by the Medical Research Council, and the Radiotherapy—Adjuvant versus Early Salvage [RAVES] trial, conducted by the Trans Tasman Radiation Oncology Group). Pending the results of these trials, **adjuvant therapy should be strongly considered for patients with multiple or very high-risk tumor features—that is, extensive extracapsular tumor extension, multiple or broad-based positive surgical margins, seminal vesicle invasion, and lymph node metastases.** For patients with focally positive margins or minimal extracapsular tumor extension, monitoring PSA every 4 months with early salvage therapy being initiated when the PSA reaches 0.2 ng/mL and is verified to be rising may be more appropriate. In patients with a limited life expectancy, and especially those with Gleason grade 6 or 7 tumors, PSA levels may be monitored to measure the PSA velocity to help determine whether salvage radiotherapy is necessary (Cotter et al, 2011; Karlin et al, 2013).

Side Effects of Adjuvant Radiotherapy

Side effects of adjuvant radiotherapy include a 5% to 10% risk of radiation proctitis or cystitis and a 50% probability that **return of erectile function will be materially compromised.** Radiotherapy also can compromise borderline postoperative urinary continence, but radiotherapy-induced incontinence is relatively uncommon if therapy is delayed until normal urinary continence is well established (Van Cangh et al, 1998; Suardi et al, 2014). The dose of salvage radiotherapy that provides a balance between risks and benefits is not well defined. It has been suggested that, compared with a dose of 66 Gy, a dose of 70 Gy might be optimal in those without local recurrence. Higher doses may be needed in the presence of local recurrence (Shelan et al, 2013). Pending return of continence, ADT can be instituted to reduce the risk of tumor progression. Some patients with highly unfavorable prognostic features with distant metastases, in whom treatment is more likely to fail, probably derive significant benefit from postoperative ADT.

Combined Androgen Deprivation Therapy and Radiotherapy

In high-risk patients who opt for postoperative radiotherapy, **there is controversy about whether they also should receive ADT.** Clinical trials are underway to answer this question. The disadvantages of adding ADT in this setting are the expense and associated side effects. A prospective, randomized trial has demonstrated significantly improved survival in patients with lymph node metastases treated with early ADT (Messing et al, 1999). In a randomized trial of ADT plus radiotherapy versus radiotherapy alone, there was a survival advantage for patients receiving 6 months of ADT. However, all the benefit was observed in patients with no or minimal comorbidities. Men with comorbidities fared worse with ADT (D'Amico et al, 2008).

An increased risk of cardiovascular death has been reported to be associated with ADT (Tsai et al, 2007). In contrast, other studies have found no difference in fatal cardiac events with 4 months of ADT (Roach et al, 2008). A meta-analysis of eight randomized trials in men with unfavorable, nonmetastatic prostate cancer with a median follow-up of 7 to 13 years reported that the cardiovascular death rate was the same in those treated and those not treated with ADT. ADT was associated with lower prostate cancer-specific and all-cause mortality rates. Although randomized trials may not reflect comorbidity in the general population, these results allay some concern regarding the risks of giving ADT with radiotherapy (Nguyen et al, 2010, 2011).

Despite the conflicting results, patients should undergo cardiac risk evaluation before beginning ADT, particularly those with high-risk disease for whom 2 to 3 years of ADT is considered standard (Shelan et al, 2013). It is relevant that dose-escalated salvage radiotherapy (70 Gy) without ADT also has been reported to achieve good biochemical control (Shelan et al, 2013).

Preoperative Radiotherapy for High-Risk Prostate Cancer

Preoperative radiotherapy may have advantages over postoperative treatment. A phase I study for high-risk prostate cancer demonstrated no dose-limiting toxicity with 54 Gy given preoperatively (Koontz et al, 2013).

Comparison of Radiotherapy with Radical Prostatectomy

An important limitation of radiotherapy as a curative modality is tumor heterogeneity with respect to radiation sensitivity. Tumor persistence within the fields of radiation may occur in up to 40% of patients with clinically localized prostate cancer treated with radiation therapy (Stone et al, 2007b; Zelefsky et al, 2008; Crook et al, 2009). Thus in many patients there are some tumor cells that are not eradicated by therapeutic doses of radiation (Kaplan et al, 2008). Accordingly, even if the tumor is confined to the prostate, radiotherapy might not eradicate it. In one study, despite high-dose (>75 Gy) 3D-CRT, nearly half of patients had cancerous biopsy

findings more than 2.5 years after treatment (Zelevsky et al, 2011). In addition, cancerous biopsy findings after treatment are usually associated with a poor prognosis (Scardino and Wheeler, 1985; Stone et al, 2007b; Zelevsky et al, 2008). The patterns of failure after surgery are different from those after radiotherapy. No modality affords 100% local control. Surgery is more likely to fail at the margins, and radiotherapy is more likely to fail in the center of the tumor. The strategies of using ADT, dose escalation, and better dose placement are designed to improve the central local control.

A study of men treated with radiotherapy for stage T1 to T3 disease with a minimum follow-up of 23 years revealed that more than two thirds developed recurrence, and more than half died of prostate cancer. Half of the recurrences occurred after 10 years, and some recurrences developed after 20 years; however, late recurrences might represent a new primary tumor (Swanson et al, 2004).

A systematic overview of radiotherapy for prostate cancer involving more than 150,000 patients reported that there are no randomized studies to compare the outcomes of radiotherapy with radical prostatectomy for patients with low-risk disease. Risk-group comparisons of T stage, Gleason score, and PSA value have reported similar results between radiotherapy and surgery; however, different end points were used to define treatment failure (Nilsson et al, 2004). For instance, in applying the ASTRO criteria to patients treated with radical prostatectomy, the respective 5-, 10-, and 15-year progression-free rates improved from 85%, 77%, and 68% to 90%, 90%, and 90%, respectively (Gretzer et al, 2002). Similarly, in a study of conventional external beam radiotherapy in men with clinical stage T1 to T2 disease treated from 1991 to 1993, freedom from progression by use of the ASTRO criteria was 49% with backdating the time of recurrence and 42% without backdating (Zietman et al, 2004). A retrospective comparison of treatment success in low- and intermediate-risk disease of brachytherapy alone versus radical prostatectomy with or without postoperative radiotherapy reported similar prostate cancer-specific mortality (0.5%), but the median follow-up was only 2 years (Arvold et al, 2011).

The use of PSA nadir of 0.2 ng/mL for patients treated with combined external beam therapy and brachytherapy has been recommended. Failure to achieve this nadir by 60 months almost always is associated with persistent disease (Critz, 2002). However, because external beam radiotherapy is more organ sparing than brachytherapy, post-treatment PSA levels are usually higher in patients treated with external beam radiotherapy only, and thus these patients might not easily achieve a nadir of 0.2 ng/mL.

Valid comparisons of radical prostatectomy with radiotherapy using current treatment methods are lacking. However, the available evidence suggests that radical prostatectomy is more effective in achieving long-term progression-free survival in patients with clinically localized disease (Hoffman et al, 2013). In a population-based study of long-term survival in nearly 60,000 patients with clinically localized prostate cancer from the SEER cancer registry, radical prostatectomy yielded better results than radiotherapy (Lu-Yao and Yao, 1997). However, more favorable results from both treatments would be expected in the PSA era with recent technical advances in surgery and radiotherapy.

A comparison of health-related quality of life after primary treatment of localized prostate cancer in patients and spouses from multiple centers from 0 to 2 years after radical prostatectomy, brachytherapy, or external beam radiation therapy revealed that adjuvant ADT with radiotherapy was associated with worse quality-of-life outcomes. Patients receiving brachytherapy reported having more long-lasting urinary irritation, bowel and sexual symptoms, and transient problems with vitality or hormonal function. The adverse effects of prostatectomy on sexual function were mitigated by nerve-sparing procedures. After prostatectomy, urinary incontinence was observed in some patients, but urinary irritation and obstruction improved, particularly in patients with a large prostate gland. External beam radiotherapy was associated with less urinary irritation and more rectal side effects. Each treatment is associated with a distinct pattern of change in quality-of-life domains related to urinary, sexual, bowel, and hormonal function. These changes influenced satisfaction

with treatment outcomes among patients and their spouses or partners (Sanda et al, 2008). Evidence shows continued declines in functional outcomes over 15 years for both radical prostatectomy and radiotherapy (Resnick et al, 2013).

Secondary Radiation-Induced Malignancies

Concerns have been raised over the development of new primary prostate cancers and highly aggressive second malignancies after radiation therapy in about 1 of 70 patients living more than 10 years after treatment with radiotherapy for prostate cancer, especially radiation-induced cancers of the bladder and rectum; however, the true magnitude of risk is difficult to quantify (Herr and Carver, 2008; Oh and Sandler, 2008; Abdel-Wahab et al, 2009; Murray et al, 2013). A comparative study of second cancers after brachytherapy or radical prostatectomy compared with the general population with a median follow-up of 7.5 years revealed no increase in bladder cancer after brachytherapy, perhaps because of the limited follow-up or the fact that the radiation dose to surrounding tissues is less with brachytherapy (Hinnen et al, 2011).

KEY POINTS: RADIOTHERAPY

- External beam radiotherapy uses gamma radiation beams directed at the prostate and surrounding tissues through multiple fields. To minimize radiation injury to the bladder and the rectum, 3D-CRT, IMRT, image-guided radiotherapy, SBRT, and proton beam radiotherapy have been developed. Patients with a high PSA level, high Gleason score, or large-volume tumor benefit from ADT in conjunction with radiotherapy. Currently, the most frequently used definition to determine treatment success after radiation therapy is the Phoenix definition, which requires PSA increases of 2 ng/mL above the nadir PSA level.
- With brachytherapy, radioactive seeds or needles are implanted directly into the prostate gland to deliver a high dose of radiation to the tumor while attempting to spare the bladder and the rectum. Brachytherapy is used primarily for the treatment of patients with clinically localized prostate cancer, but it is seldom used for the treatment of high-volume, high-risk prostate cancers. Urinary symptoms are more common after brachytherapy than after external beam radiotherapy, especially in patients with prostatic hyperplasia.
- Adjuvant radiotherapy shortly after surgery is most likely to benefit patients with extensive positive surgical margins or extracapsular tumor extension without seminal vesicle invasion or lymph node involvement. Patients most likely to have favorable responses to salvage radiotherapy are those with PSA recurrence long after surgery, slowly rising PSA level, low-grade tumor, and no seminal vesicle invasion or lymph node metastases. However, mortality benefits have also been demonstrated in patients with rapid PSA doubling times and high-risk tumors. Adjuvant radiotherapy reduces relapse rates in patients with high-risk tumor features but does not increase overall survival. Early salvage radiotherapy produces durable responses in most patients with intermediate-risk tumor features. It is unknown whether early adjuvant radiation is better than delayed salvage therapy in patients with adverse pathology findings after radical prostatectomy.

OTHER TREATMENTS

Primary Hormone Therapy

Please see the Expert Consult website for details.

In the past, primary ADT had been used extensively in the treatment of men with localized prostate cancer, especially older men, those with significant medical comorbidities precluding the use of curative therapy, and those who did not wish to undergo curative therapy (Cooperberg et al, 2003; Shahinian et al, 2005). However, it is far less frequently used today because studies suggested increased risks of diabetes mellitus, cardiovascular disease, and osteopenia leading to fractures (Krupski et al, 2004; Saigal et al, 2007; Tsai et al, 2007; Keating et al, 2012). In addition, a recent study of more than 15,000 men with early-stage prostate cancer found that those who received primary ADT instead of surgery or radiotherapy did not live any longer than those who received no treatment (Potosky et al, 2014). Studies of patients matched on propensity to receive ADT did not find an increased risk for cardiovascular mortality with ADT, suggesting that unmeasured factors affecting treatment selection may confound the association (Alibhai et al, 2009; Efsthathiou et al, 2009; Kim and Freedland, 2010; Punnen et al, 2011). Nevertheless, because of these concerns, **primary ADT is not endorsed by the AUA Best Practice Guidelines or by the NCCN guidelines (Thompson et al, 2007; National Comprehensive Cancer Network, 2014).** Moreover, the American Society of Clinical Oncology practice guidelines did not make a strong recommendation for early ADT, even in patients with positive lymph nodes, because of the concern that any decrease in prostate cancer–specific mortality might be offset by an increased risk of nonprostate cancer mortality, with no overall survival benefit (Loblaw et al, 2007; Saigal et al, 2007).

ADT can be used for patients who need symptomatic palliation and who are unfit for curative therapy (Droz et al, 2010). There are limited published contemporary data of men treated with primary ADT for clinically localized prostate cancer. In a large population-based Medicare cohort study, primary ADT did not improve survival among the majority of elderly with localized prostate cancer compared with conservative management (Lu-Yao et al, 2008). However, it could not be ruled out that, in this study, men with higher-risk disease were more likely to have been treated with primary ADT; thus it is not possible to exclude a potential benefit of primary ADT.

A trial of antiandrogen monotherapy with high-dose bicalutamide in patients with localized or locally advanced prostate cancer found that survival was improved in patients treated with radiotherapy (presumably a synergistic effect); however, there was no benefit for patients treated with surgery, and antiandrogen monotherapy may be harmful in patients managed with surveillance, again suggesting that it may not be beneficial overall when used as the only treatment (Iversen et al, 2010).

KEY POINTS: PRIMARY HORMONE THERAPY

- Primary ADT is no longer regarded as appropriate definitive therapy for men with clinically localized prostate cancer, although it may be acceptable for select older men with evidence of progressive disease who have significant medical comorbidities that preclude the use of curative therapy, or those who do not wish to undergo curative therapy. Cardiovascular evaluation is prudent before treatment of men at risk for cardiovascular complications.
- Neoadjuvant preoperative ADT reduces the rate of positive surgical margins but does not significantly affect disease progression, except perhaps in selected patients with very high-risk disease.
- ADT therapy is never curative; nevertheless, many patients experience long-term remissions. Bilateral orchiectomy and estrogen administration have largely been replaced by luteinizing hormone–releasing hormone analogues. Antiandrogens produce less sexual dysfunction and osteoporosis but have a greater risk for adverse cardiovascular complications. Newer agents are currently being integrated into clinical practice.

Cryoablation

In 2008, an AUA Best Practice statement recognized cryoablation of the prostate as an established treatment option for men with newly diagnosed or radiorecurrent organ-confined prostate cancer. Cryoablation has been used as primary whole-gland therapy, as a salvage treatment option after radical prostatectomy or radiotherapy (Babaian et al, 2008), and as focal therapy for low-risk prostate cancer (see section on focal therapy). In general, patients with clinical stage T1c to T2 disease who have a life expectancy greater than 10 years, who have no evidence of metastatic disease, and who are not concerned with potency are considered candidates for whole-gland primary cryoablation. The role of cryoablation remains undetermined for patients with clinical stage T3 disease (Babaian et al, 2008).

Third-generation cryoablation is a procedure in which 12 cryoablation needles are stereotactically inserted through the perineum into the prostate with transrectal ultrasound guidance under general or spinal anesthesia. Argon gas is then used to cool the tissue to below -40°C . An ice ball forms in the tissue, and its expansion is monitored by transrectal ultrasonography. Simultaneously, a warming Foley catheter is inserted to protect the urethra and helium gas is used to warm and preserve the prostatic urethra. The rectum can be protected by injection of a saline solution in the space between the prostate and the rectum. A double freeze-thaw cycle results in more extensive tissue damage and cell death than a single cycle.

The proposed advantages of cryoablation are that it is minimally invasive, it does not involve radiation exposure or surgical risk, repeated treatments are possible, and preservation of potency is possible in some patients (Asterling and Greene, 2009).

Cryoablation can target the whole prostate gland or can be performed as a focal treatment, usually freezing half of the prostate (Finley et al, 2010). Many patients receive ADT before treatment. Some reports have claimed oncologic effectiveness equivalent to other conventional treatments for clinically localized prostate cancer (Bahn et al, 2002; Donnelly et al, 2002; Elkjaer and Borre, 2014); however, other studies have reported that the outcomes are not as good as with radiotherapy or surgery (Roach, 2010b).

Whole-Gland Primary Cryoablation

Cryoablation has been reported to be a safe, effective alternative as primary treatment for localized prostate cancer (Lian et al, 2011) and has been advocated in elderly men who may have underlying comorbidity that precludes radical prostatectomy (Loeb et al, 2007; Chin et al, 2012). Cryoablation is more suited for less bulky prostate cancer. Patients with gross extracapsular tumor extension or seminal vesicle invasion are usually treated with neoadjuvant hormone therapy to reduce the tumor volume and allow for easier inclusion within the ice ball; however, to date, there are no data to suggest that neoadjuvant or concurrent ADT improves postcryoablation outcomes.

There is no universally accepted definition for treatment failure after cryoablation, and in many studies the Phoenix or ASTRO definitions used with radiotherapy have been applied for this purpose. The Phoenix definition is claimed to be the best predictor of tumor recurrence (Pitman et al, 2012). The justification for using the Phoenix criteria is that prostate epithelial cells surrounding the urethra that are spared during cryoablation continue to produce PSA after treatment. Thus it might be argued that a small increase in PSA might not necessarily indicate tumor progression. In practice, an undetectable PSA level is seldom attained after cryoablation; hence, definitions of biochemical recurrence used for radiotherapy are not really appropriate for ablative treatments such as cryoablation. This is because a therapy that completely ablates tissue should result in lower post-treatment PSA level than radiotherapy that eradicates cancer cells but spares nonablated normal prostate tissue. Biochemical recurrence-free rates of 60% to 90% at 5 to 10 years of follow-up after cryoablation have been

reported (Long et al, 2001; Bahn et al, 2002; Donnelly et al, 2002; Prepelica et al, 2005; Cohen et al, 2008; Jones et al, 2008; Sverrisson et al, 2014). However, the use of the Phoenix definition could overestimate the effectiveness, as failure would not be declared by this definition until the PSA level rose by 2 ng/mL, and failure ultimately occurs in many patients who do not achieve a post-treatment PSA level of less than 0.6 ng/mL (Levy et al, 2009).

In many cryoablation programs, part of the follow-up protocol is biopsy at 3 to 6 months and again in 2 to 5 years after the treatment. Post-treatment positive biopsy rates of up to 47% have been reported (El Hayek et al, 2008; Donnelly et al, 2010; Ko et al, 2010; Lian et al, 2011; Chin et al, 2012), with most being in the range of 20% (Sverrisson et al, 2014). It is noteworthy that in some cases, positive biopsy rates have been calculated by dividing the number of positive biopsies by the number of patients in the entire treated cohort, including in the denominator those who did not undergo biopsy, thus diluting the positive biopsy rate. In some studies, only patients requiring subsequent intervention with radiotherapy or ADT were considered treatment failures, and patients who underwent repeat cryoablation for positive biopsy were not considered treatment failures unless they required other treatment modalities or failed by the ASTRO criteria.

Conflicting results have been reported on comparisons of cryoablation with other primary treatments for localized prostate cancer (Chin et al, 2008; Donnelly et al, 2010). Reports from the Cryo On-Line Database (COLD) Registry consisting of case report forms from selected patients who were treated with cryoablation have, in general, reported favorable treatment results with short-term follow-up. In contrast, a single-institution study comparing the outcomes from radical prostatectomy and cryoablation performed during the same period found that cryoablation had less favorable disease-free survival, regardless of the risk subgroup (Caso et al, 2012). A reason for the higher recurrence rate with cryoablation could be that in leaving the urethra in situ, some cancer cells may remain, and some benign periurethral prostatic epithelial cells might subsequently transform into cancer. The other more likely cause of the high recurrence rate is a high rate of insufficient treatment margins, especially peripheral margins.

Complications of cryotherapy have included urinary incontinence, urethral sloughing, osteitis pubis, transient penile paresthesia, perineal and rectal pain, rectal fistula, the need for a transurethral resection of the prostate for urinary obstruction, and erectile dysfunction (Pisters et al, 2008). Studies have reported conflicting evidence regarding comparisons of urinary and sexual bother with cryoablation compared with radical prostatectomy or radiotherapy (Donnelly et al, 2010; Malcolm et al, 2010; Caso et al, 2012); however, a preponderance of evidence indicates that cryoablation is associated with more erectile dysfunction (Asterling and Greene, 2009; Roach, 2010a). Approximately one third of previously potent men treated with whole-gland cryoablation might be expected to be potent after cryoablation. The morbidity profile is improved with current argon-based technology; however, a sudden death from argon gas emboli during prostate cryoablation has been reported (Sandomirsky et al, 2012). Complications associated with salvage cryoablation are more frequent than for primary treatment (Bales et al, 1995; Perrotte et al, 1999; Pisters et al, 1999). Adverse effects are less frequent than for HIFU treatment, but potency results are less favorable, being around 15% to 40% (Asterling and Greene, 2009).

Whole-Gland Salvage Cryoablation

Cryoablation has been used for salvage therapy in patients in whom radiotherapy, radical prostatectomy, or initial treatment with cryoablation has failed (Wenske et al, 2013) and who have a negative metastatic workup (Ismail et al, 2007; Pisters et al, 2009). However, because of the necessary preservation of a thin rim of periurethral tissue for whole-gland ablation or from a more substantial spared portion of the gland with subtotal treatment, the likelihood of cure is limited. The first post-treatment PSA is prognostic of treatment

failure; a PSA level of 0.5 ng/mL or lower correlates with a good outcome (Levy et al, 2009). Some studies have reported excellent survival outcomes and minimal associated morbidity. Others have reported that the main potential advantage of salvage cryoablation may be that it could delay the need for hormone therapy (Ng et al, 2007). Five-year biochemical recurrence-free survival rates after salvage radical prostatectomy have been reported to be more favorable than for salvage cryoablation or brachytherapy. As yet, there are no meaningful long-term outcome data for salvage cryoablation, such as prostate cancer-specific survival or overall survival (Spiess et al, 2013).

In summary, there is no substantial evidence to support cryoablation over the other therapeutic treatment options. Current cryoablation methods have a lower complication rate than earlier methods, but their effectiveness at achieving cancer control is not established. The reported results for salvage after radiotherapy are inferior to those reported for salvage radical prostatectomy. In many studies, the PSA results are confounded by concomitant hormone therapy. There remains concern about viable cancer cells near the warmed urethra, and, in general, the evidence for efficacy and safety in the literature is of limited quality.

High-Intensity Focused Ultrasound Ablation

Acoustic energy can be used with ultrasound focusing to generate heat within the prostate gland, thus ablating focal lesions or the entire gland. Transrectally applied HIFU can elevate the tissue temperature of the prostate up to 100°C (Madersbacher et al, 1995). Within several seconds, a lesion develops with a sharp and predictable volume, leaving the surrounding tissue intact. Mechanisms of action of HIFU involve mechanical interaction of ultrasound waves with tissue, producing coagulating heat, high pressure, cavitation bubbles, and chemically active free radicals that ultimately induce tissue destruction by coagulation necrosis (Chapelon et al, 1999). Days to months are required for necrosis and cavitation to occur. Because HIFU energy is nonionizing, treatment can be repeated.

Treatment is performed with use of general or spinal anesthesia and takes 1 to 4 hours, depending on the prostate volume, which should not exceed 40 mL. The rectal mucosa is cooled (Blana et al, 2004), and a limited transurethral resection of the prostate or a bladder neck incision is often performed at the beginning of the procedure to reduce the risk of postoperative urinary retention (Chaussy and Thuroff, 2003). Most patients require a urethral or suprapubic catheter for several days to weeks. Two commercially available devices for HIFU are most commonly used (Thuroff et al, 2003; Uchida, 2005; Uchida et al, 2005).

HIFU is usually well tolerated; the most common side effect is acute urinary retention, occurring in about 20% of patients. Other potential complications are urinary fistula (2%), incontinence (up to 10%), and erectile dysfunction (20% to 60%), in addition to dysuria, urethral stricture, and perineal pain (Blana et al, 2004; Pickles et al, 2005). One study reported a post-treatment potency rate of 25% (Ganzer et al, 2013). HIFU should be reserved for men with a life expectancy of less than 10 years and for whom sexual function is not an important issue (Marien et al, 2014). Re-treatment of patients is associated with an increase in urinary side effects, but sexual side effects are not significantly increased (Berge et al, 2014).

Clinical studies have reported mixed results regarding the efficacy and safety of HIFU therapy. An early multicenter HIFU study reported 83%, 72%, and 52% progression-free survival rates according to the Phoenix definition for progression in low-, intermediate-, and high-risk disease, suggesting equivalent results to external beam radiotherapy (Crouzet et al, 2010). The progression criteria used were any cancerous biopsy finding or a PSA rise of more than 0.4 ng/mL, but the durability of responses has not been documented (Blana et al, 2004).

HIFU has also been used to treat patients after radiotherapy failures, but limited results have been reported (Gelet et al, 2001).

Early outcomes reflect the risk characteristics of the tumors before radiotherapy. Adverse effects associated with salvage HIFU include rectourethral fistula, severe incontinence, and bladder neck contracture (Warmuth et al, 2010).

Negative biopsy rates have been reported in 64% to 93% of patients, PSA levels below 0.5 ng/mL in 55% to 84%, and 5-year progression-free survival in 60% to 70%. The most common complications were stress incontinence, infection, stricture, and erectile dysfunction (Rebillard et al, 2008). Current complication rates are lower than previously reported because of technical improvements and the frequent performance of transurethral resection of the prostate before HIFU (Rebillard et al, 2008).

Overall, there is insufficient information to recommend HIFU as a standard therapy for clinically localized prostate cancer. The preponderance of current evidence suggests that HIFU does not provide cancer control equivalent to surgery or radiotherapy. For instance, in a small series of patients treated with one commercially available device and no adjuvant hormone therapy (Koch et al, 2007), 10% of patients developed urinary retention after treatment, 20% were incontinent, and 5% had a rectal injury. Only 42% achieved PSA below 0.5 ng/mL and negative biopsy findings. On the other hand, HIFU has been extensively studied in Europe, where it is no longer considered experimental. The results with different machines may not be equivalent. The published reports from Europe are confounded by deficiencies in study design, inhomogeneous patient populations, undersampling of the prostate on biopsies, and frequent use of transurethral resection of the prostate and androgen ablation therapy. These limitations make it impossible to know the true safety or efficacy of HIFU (Koch et al, 2007).

More recently, a large multicenter French study with short follow-up and using the Phoenix definition for failure suggested that HIFU results were equivalent to those of external beam radiotherapy (Crouzet et al, 2010). Biopsy-proven recurrences occurred in 20% of patients with short-term follow-up. The long-term results of HIFU were recently reported in a retrospective review from one center (Ganzer et al, 2013). The actuarial biochemical disease-free survival results were favorable, and the PSA nadir after HIFU was predictive of biochemical failure.

In contrast, poor results with HIFU were shown in a British study of 42 patients with a 2-year follow-up (Challacombe et al, 2009). There was a 48% failure rate and one prostate cancer death; three severe strictures; two fistulae in salvage cases; and three cases that could not be performed because of rectal wall thickness. These investigators abandoned their HIFU program.

It is feasible to perform salvage radical prostatectomy after HIFU with acceptable tumor control, but the salvage complications are similar to those of salvage prostatectomy after radiotherapy (Lawrentschuk et al, 2011).

Focal Therapy for Prostate Cancer

Please see the Expert Consult website for details.

Focal Laser Ablation

Please see the Expert Consult website for details.

Photodynamic Therapy

Please see the Expert Consult website for details.

RECOMMENDATIONS FOR TREATMENT BY PATIENT RISK GROUP

The tumor is staged at the time of diagnosis, and the patient evaluated for comorbidities. The legitimate treatment options and their associated risks and potential benefits are discussed (Tables 112-1 and 112-2). Choice of therapy for an individual patient depends on the availability of high-quality delivery.

Focal therapy has been proposed as an alternative to active surveillance or radical treatment for localized prostate cancer (Marien et al, 2014; van den Bos et al, 2014). However, because prostate cancer is usually multifocal, the fundamental rationale of focal therapy is questionable. Some authors have reported that only the main “index” lesion is likely to progress. However, it has been argued that only 20% of prostate cancers are unilateral and unifocal; there is no reliable imaging modality to rule out aggressive disease; there is no proof that only the index lesion is the potentially lethal tumor; and 50% of prostatectomy specimens in patients with low-risk disease are found to have Gleason pattern 4 disease (Black, 2009).

Several different forms of thermal energy have been used for focal treatment of prostate cancer, including cryoablation, HIFU, laser ablation therapy, radiofrequency ablation, and photodynamic therapy (PDT). In implementing these different focal therapies, varying protocols for patient selection, follow-up, and outcomes have been used. This makes it challenging to make comparative assessments among treatments.

The results of a consensus project on focal therapy trial design in prostate cancer were recently reported (van den Bos et al, 2014). It was recommended that focal therapy should not be offered to patients with clinically insignificant disease who may not benefit from active treatment and in whom focal therapy could be considered overtreatment. Thus, patients with clinically localized Gleason score 3 + 4 disease are appropriate candidates for focal therapy. Nomograms and multiparametric MRI scans that may help identify regions of the prostate that do or do not need treatment may be used to help avoid including patients with lymph node metastases; however, patient age and the PSA density were not recommended as inclusion criteria. Furthermore, it was recommended that there be no limit to the size of the prostate treated, except in the case of HIFU, wherein treatment is not recommended for a prostate exceeding 40 mL. The primary end point of focal therapy should be focal ablation of clinically significant disease (defined as a dominant tumor >0.5 mL) with negative biopsy results at 12 months after treatment. A combination of biochemical, histologic, and imaging results can be used to evaluate tumor control achieved by focal treatment. Follow-up should include periodic PSA measurements and ultrasound-guided systematic whole-prostate biopsies and also targeted biopsies to be performed 6 to 12 months after treatment. Treatment failure is categorized as “in-field” or “out-of-field.” Low-grade, low-volume tumor foci (<3 mm, Gleason 3 + 3) found out of field are not designated as failures. In addition, complications of therapy and the patient’s functional status should be assessed. An accurate definition of biochemical failure cannot be made based on validated data at this time. Phase II and phase III trials of focal therapy are currently underway.

Focal Cryoablation

Focal targeted therapy has been proposed as a potential treatment for localized prostate cancer in an attempt to reduce morbidity, especially for patients who would otherwise be candidates for active surveillance (Ward and Jones, 2012; Durand et al, 2014). However, focal therapy relies on accurate tumor localization to achieve total tumor ablation. Extended pattern prostate biopsy

fails to provide reliable localization of tumors to specific regions of the prostate (Schulte et al, 2008). Therefore it is difficult to select which individual patients should be treated and where in the prostate to treat focally based on a prostate biopsy (Catto et al, 2011).

Favorable early results of focal cryoablation have been reported; however, results reported from the COLD Registry are confounded by selection bias. A matched-pair comparison of focal cryoablation and radical prostatectomy reported similar oncologic outcomes with short follow-up (Bahn et al, 2012); nevertheless, the drawbacks of this comparison were the definition of recurrence used and the short follow-up. Despite the promising data that continue to emerge for subtotal (including focal) cryoablation, **overall clinical experience is limited and long-term results are largely unavailable.** Focal salvage cryoablation is experimental.

Focal High-Intensity Focused Ultrasound Ablation

A pilot trial of focal HIFU was reported in which 60% or more of the prostate was ablated, treated locations were determined by MRI and template mapping biopsy, and the primary end point was only adverse events. Of the patients, 73% were hospitalized for less than 24 hours (Ahmed et al, 2012). The authors reported that 89% of patients had erections sufficient for penetration, 100% had continence at 12 months, and many had significantly decreased lower urinary tract symptoms. Positive biopsy results were present at 6 months in 23%. A commentary on this study pointed out that the study was small with short follow-up and no controls (Challacombe et al, 2012). The patients had very low-volume disease and might have fared equally well without side effects on active surveillance. The HIFU technique used requires a suprapubic catheter and carries a risk of urinary retention. Of the men treated, 17% had a urinary tract infection, 1 went into urinary retention, and 1 had a potentially devastating fistula; 39% had hematuria and 22% had dysuria. Moreover, only 30 of 39 men were free of cancer at 6 months, and 4 required re-treatment. **These results are substantially worse than those of radical prostatectomy or radiotherapy.**

Radiofrequency Interstitial Tumor Ablation

Radiofrequency interstitial tumor ablation (RITA) is a noninvasive technique for patients whose comorbidity precludes procedures that require general anesthesia or hospital admission. Heating prostate tissue to temperatures substantially above 38°C destroys it nonselectively, whereas some claim that *hyperthermia* at less elevated temperatures kills cancer cells selectively. **RITA-induced hyperthermia has been investigated as a treatment of the primary tumor, in combination with radiotherapy, and for salvage after radiotherapy failure** (Prionas et al, 1994; Zlotta et al, 1998; Shariat et al, 2005).

This office-based treatment can be repeated. Careful and constant monitoring is critical to limit the risk of damage to normal tissue (Shariat et al, 2005). Advantages claimed for hyperthermia are that it can be repeated and does not preclude the use of other therapies. However, **long-term data on complications and cancer control are not available** (Beerlage et al, 2000).

Laser-induced thermal therapy is a minimally invasive ablation technique that uses laser light to deposit high-energy photons locally in tissue, causing tissue destruction through rapid heating (McNichols et al, 2004). Energy is delivered to the prostate using laser fibers inserted transperineally through needles, most commonly under MRI guidance (Reynier et al, 2004). Focal laser ablation action is based on a photothermal effect. The technologically more advanced 980-nm diode lasers are increasingly used (Colin et al, 2012). Monitoring of the procedure can be achieved by using fluoroptic thermometry next to critical structures, such as the prostate apex or near the rectum, or by using magnetic resonance thermometry (Woodrum et al, 2010).

Focal laser ablation is a potential tool for focal therapy of low-risk prostate cancer. Precision, real-time monitoring, MRI compatibility, and low cost of an integrated system are the suggested advantages of this therapy. The feasibility and safety of this technique have been reported in phase I studies (Oto et al, 2013). In one study the procedure took 2.5 to 4 hours to complete. In this study, one third of the patients had a significant decrease in erectile function 6 months after treatment. Few data have been reported on other adverse effects and outcomes. Approximately 20% to 25% of patients had positive biopsy findings in the treated region of the prostate.

PDT is based on tumor cell destruction by light emitted from a laser fiber interacting with a photosensitizing drug delivered to the tumor tissue. The photosensitizing agent is administered intravenously and is activated by light from optical fibers inserted transperineally into the desired region of the prostate under transrectal ultrasonographic guidance (Kasivisvanathan et al, 2013). The absorption of a laser photon by the photosensitizing agent leads to a chain reaction that releases a singlet oxygen and antioxidant enzymes. Singlet oxygen kills tumor cells and destroys tumor vasculature. This results in an acute inflammatory response that attracts leukocytes. It has been reported that the photosensitizing agents accumulate preferentially in cancer cells (Zuluaga et al, 2013).

There are two types of photosensitizing agents. Tissue-activated photosensitizers require hours to days to achieve therapeutic concentrations within the tumor. These agents also accumulate the skin and eyes, and can be activated within those organs for some time after administration; therefore, protection of the skin and eyes against light is required. Vascular-activated photosensitizers have the advantage of having a short drug-light interval because they achieve peak concentrations in the vasculature within minutes. Because the clearance is also rapid, patients can be discharged on the day of treatment without light protection.

The laser fiber is inserted transperineally using a brachytherapy template under ultrasound guidance. After fiber placement, interstitial illumination must be conducted in a darkened room to prevent cutaneous photosensitization. Treatment of anteriorly situated lesions may be limited by pubic arch anatomy. Oncologic treatment outcomes and side effects have not been well documented because of the limited published studies.

TABLE 112-1 Definition of Risk Group

RISK GROUP	CLINICAL STAGE	PSA (ng/mL)	GLEASON SCORE	BIOPSY CRITERIA
Low	T1a or T1c	<10	2-6	Unilateral or <50% of core involved
Intermediate	T1b, T1c, or T2a	<10	3 + 4 = 7	Bilateral
High	T1b, T1c, T2b, or T3	10-20	4 + 3 = 7	>50% of core involved or perineural invasion or ductal differentiation
Very high	T4	>20	8-10	Lymphovascular invasion or neuroendocrine differentiation

TABLE 112-2 Recommended Treatment

RISK GROUP	LIFE EXPECTANCY (YEARS)	RECOMMENDED TREATMENT
Low	0-5	AS, HT
	5-10	AS, RT, HT, O
	>10	RP, RT, AS, O
Intermediate*	0-5	AS, HT, RT, O
	5-10	RT, HT, RP, O
	>10	RP, RT, O, HT
High*	0-5	AS, RT + HT, O
	5-10	RT + HT, HT, RP, O
	>10	RT + HT, RP + RT + HT, HT
Very high*	0-5	AS, RT + HT, O
	5-10	H, RT + HT, ST
	>10	RT + HT, RP + RT + HT, HT, ST, IT

*If there is more than a 20% probability of positive lymph nodes, AS, HT, ST + HT.

AS, active surveillance; HT, hormone therapy; IT, investigational multimodal therapy; O, others; RP, radical prostatectomy; RT, radiation therapy; ST, systemic therapy.

ACKNOWLEDGMENT

The authors thank urology residents Gregory B. Auffenberg, Amanda Chao-Yu Chi, John Oliver Delancey, and Andrew S. Flum for reviewing this chapter.

113 Active Surveillance of Prostate Cancer

Herbert Ballentine Carter, MD, and Marc Arnaldo Dall'Era, MD

Natural History of Prostate Cancer in the Prostate-Specific Antigen Era

Rationale for Noncurative Management of Prostate Cancer

Observational Strategies for Prostate Cancer: Watchful Waiting and Active Surveillance

Patient and Disease Factors Affecting the Choice of and Adherence to Active Surveillance

Comparative Outcomes of Treatment and Observational Strategies

Future Research Needs

Observational strategies for prostate cancer include watchful waiting and active surveillance (expectant management). Watchful waiting was a commonly utilized approach in the era prior to prostate-specific antigen (PSA)-based screening for prostate cancer, when most men were detected at an incurable stage and available treatments were associated with a high risk of morbidity. Thus physicians and patients were anxious to avoid treatment if at all possible, waiting until the disease progressed to intervene with a palliative approach. **In contrast, active surveillance has become a standard alternative to curative intervention for select patients diagnosed through PSA-based screening in whom it is judged that the natural history of the disease will be prolonged.** For these men, surveillance is thought to offer a more targeted approach to management, avoiding unnecessary treatment and its risk of associated side effects while allowing for curative intervention for those who experience disease progression on observation.

The interest in active surveillance as a method for reducing over-treatment of prostate cancer is evidenced by a National Institutes of Health (NIH) state-of-the-science conference on this topic ([Ganz et al, 2012](#)), a major focus of which was to outline the changes in the natural history of prostate cancer that occurred with PSA-based screening.

NATURAL HISTORY OF PROSTATE CANCER IN THE PROSTATE-SPECIFIC ANTIGEN ERA

PSA-based screening for prostate cancer led to earlier detection of prostate cancer (stage migration), and thus altered the course of the disease in the absence of treatment (natural history). The incidence and prevalence of prostate cancer increased with widespread PSA testing, as did the length of time that men live with their disease, as compared to the pre-PSA era. The stage migration that occurred, with application of curative intervention at an earlier stage, undoubtedly led to a reduction in prostate cancer mortality. However, the extent to which this reduction was due to PSA-based screening is debatable ([Etzioni et al, 2008a](#)). Further, because prostate cancer progresses slowly and is found most often in older men with competing risks of mortality, the extent to which these changes in the natural history have resulted in benefit and harm is also debatable ([Carter et al, 2013](#)).

Incidence and Prevalence

The widespread adoption of PSA-based prostate cancer screening in the late 1980s, combined with transrectal ultrasound-directed needle biopsy of the prostate, resulted in a dramatic increase in the incidence of prostate cancer that peaked in 1992-1993 ([Fig. 113-1](#)

and [Table 113-1](#)). The decline in incidence between 1992 and 1995 has been attributed to removal of prevalent cases from the population that would have been detected later. It is estimated that in the United States in 2010 there were 2,617,682 men living with a diagnosis of prostate cancer ([Howlader et al, 2013](#)). The lifetime risks of being diagnosed with or dying of prostate cancer (2008-2010) were 15.33% and 2.71%, respectively (all races). By comparison, for female breast cancer the lifetime risks of developing or dying of cancer were 12.29% and 2.74%, respectively, and for cancer of the colon/rectum (both sexes) the risks were 4.82% and 1.98%, respectively ([Howlader et al, 2013](#)). The discrepancy between the risks of diagnosis and of death for prostate cancer can be attributed to the ease of detection of cancer with a low biologic potential for harm ([Thompson et al, 2004](#); [Haas et al, 2007](#)), rather than the success of curative treatment of the lethal phenotype ([Schröder et al, 2012a](#)).

In addition to changes in the incidence and prevalence of prostate cancer, there have been changes in the pathologic interpretation of biopsies in the PSA era that have altered the natural history of the disease. For example, the Gleason grading system has evolved so that Gleason scores below 6 are not assigned on needle biopsies, and cancers previously graded as Gleason score 6 are now often graded as Gleason score 7 tumors ([Epstein et al, 2005](#)). This upgrading trend made it more likely that a patient previously assigned a Gleason score of low grade would be treated based on the assignment of a higher grade. It has been estimated that the upgrading trend improved the perceived cancer-specific survival by 26% ([Albertsen et al, 2005a](#)).

Natural History of Untreated Disease

The course of prostate cancer in the absence of treatment has been evaluated both in observational studies and in randomized trials. Estimates of cancer-specific mortality derived from pre-PSA-era studies would be higher when compared to estimates from PSA-era studies because of a lead time of 5 to 10 years with PSA-based screening and because of grade inflation (see earlier).

Observational Studies

The outcomes of men with moderately differentiated (Gleason score 5-7) and poorly differentiated (Gleason score 8-10) cancers managed without treatment in the PSA era (1992-2002) and the pre-PSA era (prior to 1992) were compared ([Lu-Yao et al, 2009](#)). Ten-year cancer-specific mortality without treatment for men ages 65 to 74 years with moderately differentiated cancers (Gleason score 5-7) diagnosed in the PSA and pre-PSA eras ranged from 2% to 6% and from 15% to 23%, respectively. For men with poorly

Figure 113-1. Surveillance, Epidemiology, and End Results (SEER) Program age-adjusted prostate cancer incidence. (Modified from Howlader N, Noone AM, Krapcho M, et al, editors. TABLE 113-1 The Joinpoint Trend in Surveillance, Epidemiology, and End Results (SEER) Program Cancer Incidence with Associated Annual Percent Change for Cancer of the Prostate between 1975 and 2010, All Races

TREND*	PERIOD
2.6	1975-1988
16.5	1988-1992
-11.6	1992-1995
2.4	1995-2000
-2.0	2000-2010

*Annual percent change (%).

Modified from Howlader N, Noone AM, Krapcho M, et al, editors. SEER cancer statistics review, 1975-2010. Bethesda (MD): National Cancer Institute, http://seer.cancer.gov/csr/1975_2010/; 2013. Based on November 2012 SEER data submission, posted to the SEER website, 2013.

differentiated cancers managed without treatment, 10-year cancer-specific mortality in the PSA and pre-PSA eras ranged from 25% to 38% and from 50% to 66%, respectively. In a competing risk model, the 15-year prostate cancer mortality in the PSA era was estimated to be 0% to 2% for men ages 55 to 74 years with Gleason score 6 or less managed conservatively (Parker et al, 2006). These low-grade prostate cancers make up two of three cancers found with initial PSA-based screening, and three of four or more with follow-up screening using 1- to 4-year screening intervals (Andriole et al, 2009; Schröder et al, 2009). Thus, the pool of disease carrying a low risk of cancer-related death without treatment over a 10- to 15-year period is large with PSA-based screening.

The final report of a follow-up over 32 years of 223 men with prostate cancer managed conservatively after a diagnosis in the pre-PSA era was recently published after all but 3 men had died (Popiolek et al, 2013). At diagnosis 56% of the men were age 70 years or above and intervention per protocol was androgen withdrawal for local or metastatic progression. The important findings from this study were that 64% of men remained untreated and none of these men developed metastatic progression or died of prostate cancer. Further, progression to distant metastasis or prostate cancer death was 13.9% and 12.3%, respectively, for Gleason score 6 or below but considerably higher at 18.2% and 22.7%, 30% and 20%, and 44.4% and 55.6% for Gleason score 3+4, 4+3, and 8-10, respectively. These data and those of Albertsen and colleagues (2005b)

suggest that prostate cancer progression and mortality increase slowly up to 15 years for men with low-grade disease, but do not rapidly increase beyond that time. The increase in mortality after 15 years among men with low-grade cancers in the study with the most complete follow-up (Popiolek et al, 2013) was considered an artifact resulting from small numbers of men surviving. What is unknown is whether or not death from prostate cancer among men with low-grade cancer occurs as a result of undiagnosed (missed) higher grades of cancer or of progression of low-grade to higher-grade cancer. Population data evaluating changes in stage and grade suggest that the former is more likely (Penney et al, 2013).

Randomized Studies

The control arms of randomized trials represent an opportunity for evaluating the natural history of prostate cancer. The Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) randomized 695 men (mean age 65 years) to observation versus radical prostatectomy; 5% were diagnosed through PSA-based screening, 3 of 4 had palpable disease, and the mean PSA level was 13 ng/mL at diagnosis (Bill-Axelson et al, 2011). Recognizing that these men differ from those diagnosed today with PSA-based screening, the cumulative incidence of death from prostate cancer was 20.7% in the control group overall, and 11% for men with low-risk disease (PSA <10 ng/mL and Gleason score <7), similar to the cumulative incidence of death from prostate cancer of 12.3% at 30 years for men with Gleason score 6 cancers managed conservatively in the Swedish observational study (Popiolek et al, 2013). In the SPCG-4 study (Bill-Axelson et al, 2011), of seven men with low-risk disease who underwent surgery and died of prostate cancer, tumors in six patients were upgraded to Gleason score 7 or 8 at radical prostatectomy, further evidence that death from prostate cancer among men with low-risk disease occurs more likely from unrecognized high-grade disease rather than progression of low-grade to high-grade disease.

The Prostate Cancer Intervention versus Observation Trial (PIVOT) randomized 731 men diagnosed with localized prostate cancer to radical prostatectomy or observation (mean age 67 years; median PSA 7.8 ng/mL) (Wilt et al, 2012). In the observation group, bone metastases and prostate cancer death occurred in 10.6% and 8.4%, respectively, through 12 years. Death from prostate cancer occurred in 5.7% and 17.4% of men diagnosed with Gleason score below 7 and 7 and above, respectively, and in 6.2% and 12.8% of men with a PSA of 10 ng/mL or below and above 10 ng/mL, respectively. Stratified by D'Amico risk groups (D'Amico et al, 1998), death from prostate cancer occurred in 2.7%, 10.8%, and 17.5% of men with low-, intermediate-, and high-risk disease, respectively. Recognizing that men in the PIVOT study were more likely to have been diagnosed as a result of PSA-based testing as compared to men in the SPCG-4 study who were not, it is of interest that the cumulative incidence of death from prostate cancer in the SPCG-4 study among men with low-risk disease (11%) is comparable to that of men with intermediate-risk disease (10.8%) in PIVOT. These data could be interpreted as follows: outcomes for men with low-risk disease in the pre-PSA era are comparable with those of men diagnosed today with intermediate-risk disease, as a result of lead time with PSA-based screening and changes in the Gleason scoring system.

Stage Migration and Mortality Changes with Prostate-Specific Antigen–Based Screening

It has been well established that the addition of PSA testing to digital rectal examination results in the detection of prostate cancers that are more likely to be organ confined as compared to detection without PSA testing (Catalona et al, 1993). A trend of using lower PSA thresholds for recommending a prostate biopsy, the removal of more tissue at each prostate biopsy session, and the increasing use of multiple biopsy sessions after a negative prostate biopsy, all occurring during the PSA era, resulted in an

increase in nonpalpable, small-volume, low-grade cancers (Hilton et al, 2012). For example, Cooperberg and colleagues (2005), using data from a cancer registry, reported an increase from 30% to 47% in the proportion of men diagnosed with low-risk disease between the eras 1989-1992 and 1999-2002 while the proportion of men with high-risk disease during these same eras decreased from 37% to 16%. Coincident with the stage migration during the PSA era in the United States, there was a 75% reduction in the rate of advanced prostate cancer and a 40% reduction in the age-adjusted prostate cancer mortality (Howlader et al, 2013). However, it is difficult to know to what extent PSA-based screening or changes in treatment were responsible for the prostate cancer mortality decline. Indeed, ecologic studies have not consistently shown a relationship between PSA uptake and a decline in prostate cancer mortality (Lu-Yao et al, 2008).

Etzioni and associates (2008b) estimated that early detection as a result of screening accounted for 45% to 70% of the prostate mortality decline in the United States, and that changes in treatment explained 22% to 33% of the mortality decline (Etzioni et al, 2012). If half of the 40% mortality decline in the United States were due to PSA-based screening, the mortality reduction would approximate the relative mortality reduction of 20% that was observed in the European Randomized Study of Screening for Prostate Cancer (ERSPC) (Schröder et al, 2012b).

KEY POINT: NATURAL HISTORY OF PROSTATE CANCER IN THE PSA ERA

- Lower PSA thresholds for recommending a prostate biopsy, the removal of more tissue at each prostate biopsy session, and the increasing use of multiple biopsy sessions after a negative prostate biopsy resulted in an increase in nonpalpable, small-volume, low-grade cancers.

RATIONALE FOR NONCURATIVE MANAGEMENT OF PROSTATE CANCER

PSA-based screening and treatment of prostate cancer at a localized stage can prevent prostate cancer death for some men (Schröder et al, 2012b; Wilt et al, 2012). However, the long natural history of most prostate cancers detected through screening and the associated competing mortality risks for many older men who are diagnosed through screening provide a large reservoir for overtreatment—especially if curative intervention is the downstream consequence of every screening-detected prostate cancer. Because curative intervention is associated with functional declines in quality of life, treatment that does not prevent disease progression and/or death from prostate cancer would risk treatment-associated harm without benefit.

Functional Outcomes and Quality of Life after Treatment for Localized Prostate Cancer

Few studies have evaluated the long-term functional outcomes after treatment for localized prostate cancer. In the Prostate Cancer Outcomes Study (Resnick et al, 2013b), investigators evaluated the outcomes of men undergoing radiotherapy and surgery for localized prostate cancer after a diagnosis in 1994-1995. At 15 years, declines in urinary, sexual, and bowel function were common, with domain-specific differences between radiation and surgery at 2 and 5 years following treatment. These quality-of-life declines in urinary, bowel, and sexual function occur to a significantly greater extent among those who undergo treatment for prostate cancer as compared to a normative aging population without a diagnosis of prostate cancer, and symptom distress is more common among men with prostate cancer who are treated compared to those not treated (Mols et al, 2009; Johansson et al, 2011). Sanda and colleagues (2008) prospectively evaluated health-related quality of

life after treatment (radiotherapy and surgery) for localized prostate cancer. They reported that a substantial proportion of men did not return to baseline function in the domains of bowel, sexual, and urinary function; that changes in quality-of-life domains were treatment specific; and that patient and partner outcome satisfaction were closely associated with changes in quality of life after treatment. Thus treatment for prostate cancer commonly results in quality-of-life changes that affect both the patient and his partner.

Risks of Overtreatment of Prostate Cancer

The risk of overtreatment of prostate cancer is high when prostate cancer is discovered on prostate biopsies triggered by PSA testing—the most common scenario. Findings from the Prostate Cancer Prevention Trial (PCPT) highlight the prevalence and ease of detection of low-grade prostate cancers (Thompson et al, 2004). Fifteen percent of men at a median age of 69 years with an average PSA of 1.5 ng/mL had prostate cancer found on a sextant biopsy; 85% of these were low grade. In the PSA range (2.1 to 4.0 ng/mL) at which many men today undergo a prostate biopsy, cancer was found in 25% on prostate biopsy and 80% of these were well differentiated. These data are consistent with an autopsy study in men without a prostate cancer diagnosis at an age and PSA similar to the PCPT (Haas et al, 2007). The authors found prostate cancer in 30% of men on careful step sectioning, and an ex vivo prostate biopsy using standard techniques would have detected half of these (15%), similar to the PCPT. The high prevalence of well-differentiated cancers on prostate biopsy has major implications because of the protracted natural history of these tumors even without treatment (see earlier). Since the average age at diagnosis of prostate cancer is 67 years, an age at which a substantial proportion of men have favorable-risk prostate cancers with a prolonged natural history, the opportunity for overdiagnosis and overtreatment is high if treatment follows diagnosis in most men.

Overdiagnosis is the detection of a cancer that would otherwise not have been diagnosed in the lifetime of the host. Treatment of men who would otherwise not have known about their cancer in the absence of PSA testing is *overtreatment*. Overtreatment exacts a cost to the health care system and potential harm to a patient, with no benefit. For a previously asymptomatic patient, the cost can be substantial in terms of quality of life, and thus the bar should be high for determining the need for curative intervention.

The rate of overtreatment in the United States is similar to the rate of overdiagnosis since the majority of men undergo curative intervention after receiving a prostate cancer diagnosis (Cooperberg et al, 2010a). However, overdiagnosis estimates vary as a result of differences in the metric used for quantification of overdiagnosis, modeling approaches used for estimation of overdiagnosis, and populations studied. Estimates of overdiagnosis ranging between 23% and 42% have been reported based on U.S. incidence (Heijnsdijk et al, 2009), and estimates as high as 66% have been reported from the Rotterdam section of the ESRPC (Draisma et al, 2009). Depending upon the age at diagnosis and the risk status (PSA and grade), the likelihood that a screening-detected cancer has been overdiagnosed can vary from below 5% to more than 75% (Gulati et al, 2011).

Miller and colleagues (2006) estimated the incidence of overtreatment among older men with lower-risk prostate cancer in the United States who were unlikely to benefit from treatment and reported overtreatment rates of 10% and 45% for surgery and radiation, respectively. Recently, it was found that the use of advanced treatment technologies has increased among men in the Medicare population least likely to benefit from treatment, despite increasing awareness of the extent of overtreatment for low-risk disease (Jacobs et al, 2013). Even among older adults, treatment rates for low-risk prostate cancer are high; 59%, 36.6%, and 15.8% of patients ages 75 to 79 years, 80 to 84 years, and 85 years or older were initially treated with radiation therapy in one study using Medicare data (Mishra et al, 2014). These data highlight an important disconnect between evidence and practice given the results from randomized trials comparing treatment to no treatment. Indeed, the

overdiagnosis and overtreatment of prostate cancer greatly contributed to the U.S. Preventative Services Task Force recommendation against generalized PSA screening in 2012.

Comparative Outcomes of Surgery and Observation for Prostate Cancer

The SPCG-4 study (Bill-Axelsson et al, 2011) randomly assigned 695 men (mean age 65 years) with localized prostate cancer to radical prostatectomy or watchful waiting. Unlike men diagnosed today with screening-detected prostate cancer, only 5% were screening detected, three of four had palpable cancers, approximately one in three had Gleason scores of 7 or more, and almost half of the men had PSA levels of 10 ng/mL or more. After 15 years of follow-up, men who underwent surgical treatment had significantly lower rates of distant metastatic disease and death from prostate cancer—an absolute between-group difference of 11.7% and 6.1%, respectively. Among men below age 65 years, there was a significant absolute between-group difference in rates of distant metastatic disease and prostate cancer death of 18.3% and 9.4%. However, for men age 65 years and above, surgery did not provide a benefit in terms of freedom from metastatic disease or prostate cancer death over 15 years of follow-up. These data highlight an important aspect of prostate cancer management: the unlikely probability that treatment will improve health outcomes for older men with favorable-risk disease.

The PSA-era PIVOT (Wilt et al, 2012) randomly assigned 731 men with localized prostate cancer and a mean age of 67 years to radical prostatectomy or observation. While follow-up through 12 years revealed no all-cause or cancer-specific mortality reduction with surgery, a subset analysis suggested an all-cause mortality reduction with surgery for men with a PSA above 10 ng/mL and those with intermediate- to high-risk disease. Other-cause mortality in this trial was higher than in other trials, suggesting that men enrolled had more comorbidities that could have influenced the results. This criticism of the trial ignores the fact that more than 30% of men with a life expectancy less than 5 years and 60% of those with a life expectancy of 5 to 10 years with a diagnosis of low-risk cancer undergo treatment for prostate cancer in the United States (Daskivich et al, 2011; Raldow et al, 2011).

The findings from the SPCG-4 study and PIVOT should inform practice for older men with low-risk disease, especially those with associated comorbidities unlikely to benefit from curative intervention. For these men, no treatment may be the most rational initial management considering that harm (quality-of-life decrement) is likely to outweigh any benefit (prostate cancer mortality reduction).

KEY POINTS: RATIONALE FOR NONCURATIVE MANAGEMENT OF PROSTATE CANCER

- The overdiagnosis and overtreatment of prostate cancer greatly contributed to the U.S. Preventative Services Task Force recommendation against generalized PSA screening in 2012.
- Curative intervention is associated with functional declines in quality of life; therefore treatment that does not prevent disease progression and/or death from prostate cancer results in overtreatment with no clear benefit.

OBSERVATIONAL STRATEGIES FOR PROSTATE CANCER: WATCHFUL WAITING AND ACTIVE SURVEILLANCE

Prostate cancer is in most cases a slowly progressive disease. However, early localized disease is curable, whereas metastatic disease is not. Thus a continued debate among clinicians is whether to treat early to prevent disseminated disease, or observe and delay

treatment until there is evidence of progression. The former risks harm from overtreatment of an indolent disease, whereas the latter risks missing an opportunity for cure among those destined to experience progression. An unmet need is to identify the relatively small proportion of men with localized disease and a lethal phenotype in whom death can be prevented by curative intervention, while avoiding treatment of the large pool of men with indolent disease that can be detected with screening.

It should be recognized that large-scale, long-term comparative studies of observation versus intervention among men with screening-detected prostate cancers do not exist. While PIVOT (Wilt et al, 2012) attempted to address the benefit (or lack thereof) of surgery versus observation for localized prostate cancer in the modern era, the study was underpowered because the enrollment goal could not be achieved (Thompson and Tangen, 2012). Therefore the evidence to support observational strategies for selected men with localized prostate cancer diagnosed in the modern era is based on the long natural history of favorable-risk disease (see earlier) and single-arm studies of men managed without treatment.

A distinction can be made between watchful waiting and active surveillance. As outlined by Parker (2004), these approaches differ in primary aim, patient and tumor characteristics, treatment timing, and treatment intent. The aim of watchful waiting historically was to avoid treatment altogether among men with a limited life expectancy and advanced disease detected in an era when screening was not routine. The rationale for this approach was that, for most, death from another cause was more likely than death from prostate cancer. For these men, treatment was delayed until evidence of disease progression (local or systemic) at which time palliative treatment was initiated, most often with castration. In contrast, active surveillance encompasses a more selective approach to identifying men with favorable-risk disease at low risk of harm without treatment, with the intent to intervene for cure in those who experience disease progression while avoiding treatment-associated harm for those who do not. The ideal candidate, the approach to monitoring, and the triggers that should prompt curative intervention among those being monitored were all identified by the NIH as priorities for future research in active surveillance (Ganz et al, 2012).

Identification of Candidates for Observation

Selection of patients for observation depends upon patient and tumor metrics, as well as a patient's personal preferences (Han et al, 2012). The age, comorbidities, and estimated life expectancy of the patient are important to consider given that prostate cancer can be a slowly progressive disease that may not have time to progress in those whose remaining years of life are limited. Tools for estimating life expectancy are available and their use is encouraged (Walz et al, 2007; Mohan et al, 2011; Cho et al, 2013; Cruz et al, 2013).

In terms of tumor metrics, natural history studies clearly demonstrate that the Gleason score is a powerful predictor of the risk of disease progression and dissemination; in addition, both stage and PSA level at diagnosis provide additional information regarding risk (Table 113-2). Finally, the preference of a patient for living with cancer or the side effects of treatment should be considered in decision making (Hayes et al, 2010; Liu et al, 2012). Patients with similar disease characteristics for whom both observation and curative intervention might be reasonable may have differing personal preferences. For some, willingness to accept a decline in quality of life to be rid of a cancer that has minimal chance of causing harm over a decade or more may seem reasonable, while others would rather live with a cancer and maintain their quality of life. An understanding of a patient's personal preferences should play a large part in shared decision making (Barry and Edgman-Levitan, 2012).

Watchful Waiting

Watchful waiting is a management option for localized disease in men who are not candidates for aggressive local therapy (radiation

TABLE 113-2 Prostate Cancer Risk Stratification*

RISK PROFILE	CRITERIA†	APPROXIMATE PROPORTION OF NEWLY DIAGNOSED CASES‡
Favorable		35%
Very low risk	<ul style="list-style-type: none"> • T1c • Gleason score ≤6 • PSA <10 ng/mL • Fewer than 3 biopsy cores positive, ≤50% cancer in any core • PSA density <0.15 ng/mL per gram 	
Low risk	<ul style="list-style-type: none"> • T1 or T2a • Gleason score 2-6 • PSA <10 ng/mL 	
Intermediate risk	<ul style="list-style-type: none"> • T2b-T2c or • Gleason score 7 or • PSA 10-20 ng/mL 	33%
High risk	<ul style="list-style-type: none"> • T3a or • Gleason score 8-10 or • PSA >20 ng/mL 	32%

and surgery). Elderly men with a limited life expectancy and/or associated comorbidities could be considered ideal candidates for watchful waiting. Cancer-specific outcomes from the Swedish observation study (Popiolek et al, 2013) and those from the Connecticut Tumor Registry (Albertsen et al, 2005b) suggest that in the first 5 years of follow-up only men with the most aggressive disease (Gleason score 8-10) are at risk of prostate cancer death. Thus for men with a life expectancy below 5 years and asymptomatic localized disease, treatment should be withheld in the absence of the highest grades of cancer. Although men with Gleason scores below 8-10 could develop local symptoms, development of metastatic disease or death from prostate cancer is not likely in the absence of treatment within 5 years.

The likelihood of death from initially localized prostate cancer beyond 5 years in the absence of treatment is closely associated with patient age at diagnosis and Gleason score of the cancer (Albertsen et al, 2005b; Popiolek et al, 2013). Cancer-specific survival was more than 80% for men without poorly differentiated cancer at 10 years in the Swedish watchful waiting study, and was 65% and 28% at 15 years for those with Gleason score 7 and 8-10, respectively (Popiolek et al, 2013). Thus one could argue that, in the absence of poorly differentiated cancer, those men without a 10-year life expectancy should not be treated. The results from PIVOT comparing watchful waiting and prostatectomy generally support this conclusion (Wilt et al, 2012). However, as

compared to watchful waiting, prostatectomy resulted in absolute reductions of 9% to 11% in the rate of metastatic disease among men with PSA levels that were greater than 10 ng/mL or with intermediate- or high-risk disease at a median follow-up of 10 years (Wilt et al, 2012). One could draw several conclusions from these data. First, men with favorable-risk disease who have less than a 10-year life expectancy should not be treated for prostate cancer because harm will outweigh any benefit. Second, some men (but not most) with intermediate- and high-risk disease will benefit from curative intervention even when life expectancy is limited to 10 years or less, especially those with high-risk disease. Third, watchful waiting in men with intermediate- and high-risk disease who have more than a 10-year life expectancy may compromise the chance for cure in a substantial minority that will increase with time. Thus watchful waiting could be considered preferable for all men without high-risk disease who have less than a 5-year life expectancy, and an option for those without high-risk disease and a life expectancy below 10 years. Most urologists today would favor active surveillance (not watchful waiting) as an observational strategy for men without high-risk disease and a life expectancy of 5 to 10 years (Mohler et al, 2012).

Active Surveillance

Active surveillance as a management option for localized prostate cancer is offered to appropriate candidates who could also be offered aggressive local therapies (surgery and radiotherapy) with the intent to intervene if the disease progresses (Dall'Era et al, 2012; Bangma et al, 2013; Klotz, 2013). Active surveillance is not recommended for men with high-risk disease, or those with primary Gleason pattern 4 or 5, who have a substantial risk of harboring systemic disease at diagnosis (Eggerer et al, 2011) and of progression to metastatic disease in the absence of treatment (Wilt et al, 2012). However, active surveillance should be considered for those with very low-, low-, and intermediate-risk prostate cancer (see Table 113-2) depending on overall health state and life expectancy, as well as personal preferences. The National Comprehensive Cancer Network (NCCN) guidelines recommend active surveillance as the preferred management option for men with very low-risk disease and a life expectancy below 20 years and those with low-risk disease and a life expectancy below 10 years, and an option for those with low-risk disease and a life expectancy of 10 years or more or intermediate-risk disease and a life expectancy less than 10 years (Mohler et al, 2012).

The results of the PSA-era PIVOT that randomized men to watchful waiting versus prostatectomy suggest that men with intermediate- and high-risk disease can benefit from curative intervention within 10 years (Wilt et al, 2012). These data are consistent with the results of the SPCG-4 pre-PSA-era study that randomized men to watchful waiting versus prostatectomy and found that curative intervention significantly reduced rates of metastatic disease and prostate cancer death (Bill-Axelsson et al, 2011). The subset of men in PIVOT with intermediate- and high-risk disease are more like the men in the SPCG-4 study who were recruited in the pre-PSA era—a substantial proportion with palpable, high-grade disease and PSA levels above 10 ng/mL. Thus active surveillance among men with a life expectancy above 10 to 15 years would appear to be safest for those with very low- to low-risk disease.

The two major limitations in identifying the ideal candidate for active surveillance are (1) defining aggressive disease that will cause harm in the absence of treatment and (2) assessing disease within the prostate without removing the gland. Most agree that, without treatment, Gleason pattern 4/5 has the potential to progress beyond the prostate if given time (Albertsen et al, 2005b; Popiolek et al, 2013). However, pure Gleason pattern 3 would appear to be an indolent phenotype in most men, with limited chance of metastatic progression (Albertsen et al, 2005b; Popiolek et al, 2013). In more than 14,000 radical prostatectomies performed in men with Gleason pattern 3, no patient was found to have lymph node metastases (Ross et al, 2012). A cancer volume of less than 0.5 mL and pure Gleason pattern 3 confined to the

prostate has been considered a definition of indolent prostate cancer, and a number of schemes have been recommended for prediction of these tumors prior to treatment (Epstein et al, 1994; Steyerberg et al, 2007; Dong et al, 2008). However, there is growing recognition that this definition of indolence does not encompass a large proportion of men with more extensive low-grade disease for which treatment would be unnecessary. Thus, there is a greater focus on identifying those patients who have low-grade disease (no Gleason pattern 4/5) who can be safely monitored without immediate treatment.

Identification of patients with purely low-grade cancer is problematic at present because of disease misclassification. Currently used clinical criteria to select men for surveillance can underestimate disease grade and extent in a substantial minority of cases (Tosoian et al, 2013). Thus use of the term *progression* while on surveillance should be replaced with disease *reclassification*, since most patients meeting surveillance criteria who are found to have high-grade or more extensive disease on surveillance biopsies are thought to have been misclassified initially, rather than experiencing true disease progression (Inoue et al, 2014).

Epstein and colleagues (2012), in the largest study evaluating upgrading at radical prostatectomy in the modern era, found that 36% of men with Gleason score 5-6 on needle biopsy were found to have higher-grade disease at radical prostatectomy when tertiary grade was considered. The 10-year actuarial rate of upgrading on annual surveillance biopsies in a large active surveillance experience was approximately 30% (Tosoian et al, 2011). The similarity in the rate of upgrading at radical prostatectomy, and reclassification to high-grade disease on annual biopsies over a decade for men with low-grade cancer, strongly suggest that initial misclassification is the more common reason for reclassification on surveillance, and not “true” disease progression from low to high grade. For this reason, some have recommended “confirmatory” biopsies and/or extensive biopsy strategies with perineal brachytherapy templates to reduce the risk of biopsy misclassification prior to considering active surveillance (Barzell et al, 2012).

There is evidence that higher PSA and PSA density (volume-adjusted PSA), lower percentage of free PSA (fPSA) and higher proPSA, greater extent of low-grade cancer on biopsy (number of cores positive and percentage of positive cores), higher clinical stage, older age, black race, and suspicious findings on multiparametric magnetic resonance imaging (mMRI) are all associated with higher rates of misclassification on prostate biopsy (Tosoian et al, 2011, 2013; Carter, 2012; Stamatakis et al, 2013; Sundi et al, 2013; Cary et al, 2014). In practice, PSA, PSA density, cancer stage, and extent of low-grade cancer on prostate biopsy are most often used for selecting men for surveillance (see Table 113-2).

There is growing enthusiasm for the use of mMRI as a tool to help avoid misclassification of low-grade disease on prostate biopsy and to select men for active surveillance. The use of mMRI for biopsy targeting would appear to have higher sensitivity than transrectal ultrasound-guided systematic biopsies for cancers with Gleason scores above 6 (Turkbey et al, 2011; Hambrook et al, 2012; Siddiqui et al, 2013). Further, mMRI has been shown to have a high negative predictive value for the identification of men who will be reclassified under active surveillance (Fradet et al, 2010; Mullins et al, 2013; Hoeks et al, 2014). This technology, when used to direct prostate biopsies to suspicious areas, may be useful for excluding patients with high-grade disease from active surveillance (Sonn et al, 2014).

Definition of Progression and Triggers for Intervention on Observation

The definition of progression and triggers for intervention differ for active surveillance and watchful waiting since the goals are not the same—aggressive local therapy during a window of curability for active surveillance and palliative therapy in the face of progression for watchful waiting.

Watchful Waiting

Progression of disease among men on watchful waiting could occur as a result of local tumor growth and/or metastatic spread of disease to lymph nodes or bone. A clinician should be cognizant of the potential for local extension of disease resulting in lower urinary tract symptoms (irritative and obstructive) or upper tract obstruction from invasion into the trigone of the bladder, and for development of metastatic disease to lymph nodes or bone. Thus an evaluation that includes history and physical examination (including digital rectal examination of the prostate), PSA and creatinine measurement at 6-month intervals, and an annual bone scan would be a rational program of follow-up for these men. **While disease progression would most often be accompanied by increases in PSA, poorly differentiated cancers producing little PSA can progress without a rising PSA, especially with neuroendocrine differentiation. Thus follow-up should not rely on serial PSA measurements alone.** Symptomatic progression, evidence of upper urinary tract obstruction, or evidence of metastatic disease should trigger consideration of intervention with androgen deprivation therapy as palliative care before the development of irreversible renal or neurologic damage.

Active Surveillance

Most urologists would monitor a patient on surveillance with PSA measurement and digital rectal examination at least biannually, and perform surveillance prostate biopsies at 1- to 2-year intervals (Dall'Era et al, 2012). However, defining disease progression is problematic. Progression in active surveillance programs has been defined based on PSA kinetics or exceeding a given PSA threshold, increased extent of cancer or higher-grade disease on prostate biopsy, change in digital rectal examination, and proceeding to curative intervention. Yet PSA changes (Ross et al, 2010; Whitson et al, 2011) and exceeding a given threshold PSA value (Umbuhr et al, 2014) may not reflect progression of disease. A change in stage or digital rectal examination findings is unusual among patients with low-risk disease (Tosoian et al, 2011). Switching from surveillance to curative intervention may be triggered by a patient's personal preference or anxiety and not necessarily by a change in the cancer. Nevertheless, a younger age at entry into surveillance (Carter et al, 2003; el-Geneidy et al, 2004), higher baseline PSA (Patel et al, 2004; Eastham et al, 2008) and increasing PSA (Khatami et al, 2007), and higher clinical stage at baseline (Klotz, 2005), by baseline biopsy criteria (higher Gleason score and a higher percentage of positive cores) (Eastham et al, 2008), and on repeat biopsy results (Patel et al, 2004; Al Otaibi et al, 2008; Tseng et al, 2010) are associated with the risk of intervention in prostate cancer surveillance programs. Since cancer grade is the strongest feature associated with long-term freedom from disease in untreated men, there has been an effort to predict grade reclassification among men considered for surveillance or being monitored, through the use of prostate biopsy features, imaging, and biomarkers.

Repeat Prostate Biopsy. In a multi-institutional study that included over 23,000 men who underwent radical prostatectomy for treatment of prostate cancer, primary and secondary Gleason pattern 4-5 and seminal vesicle invasion were the strongest pathologic features predictive of prostate cancer-specific mortality (Eggener et al, 2011). **Thus the finding of high-grade disease (Gleason score 7 or higher) on surveillance biopsies has been considered a trigger for intervention in most active surveillance programs (Dall'Era et al, 2012).**

Defining progression on active surveillance based on a surveillance biopsy is difficult because of the rate of grade misclassification at diagnosis (Dall'Era et al, 2012). In a study evaluating men who underwent radical prostatectomy after a diagnosis of very low-risk disease from 2004 to 2012 (contemporary grading system), the upgrading rates to Gleason 3+4, 4+3, and 8-10 were 9%, 2.7%, and 0.9%, respectively, for Caucasians and two to three times higher for African-Americans (Sundi et al, 2013). **The risk of upgrading at radical prostatectomy is higher for men with low-risk versus**

those with very low-risk disease (Tosoian et al, 2013). For example, among men who underwent a radical prostatectomy after a diagnosis of low-risk or very low-risk disease (see Table 113-2), the rate of upgrading to Gleason score 7 or higher was 13% for very low-risk and 22% for low-risk disease, respectively (Tosoian et al, 2013). Thus the finding of high-grade disease on surveillance biopsies is more likely to represent disease misclassification at diagnosis rather than disease progression, and thus the term *reclassification* is recommended.

Biopsy reclassification on surveillance can be defined in terms of a greater extent of disease at biopsy and/or higher grade of disease at biopsy, both predictive of adverse features at radical prostatectomy (Dall'Era et al, 2012; Reese et al, 2013). The extent of cancer (number and percentage of cores with cancer and percentage of core involved with cancer) on prostate biopsy has been shown to correlate with both the extent and grade of cancer at radical prostatectomy (Epstein et al, 2012). Therefore these features are considered proxies for the presence of a higher-grade cancer for which treatment may be beneficial.

Extended Biopsy Schemes. To reduce the rate of biopsy misclassification prior to entry into active surveillance, some have recommended biopsies more extensive than a traditional 12-core sextant scheme that is generally recommended for assessment of an elevated PSA. Both transrectal saturation biopsies, sampling both transition and peripheral zones extensively, and transperineal template mapping biopsies have been evaluated.

Ploussard and colleagues (2014) compared a 21-core transrectal biopsy scheme to a 12-core transrectal approach for initial biopsies among men without a prostate cancer diagnosis and reported that detection of Gleason score cancer above 6 was no different between approaches. Linder and coworkers (2013) evaluated the ability of a 12-core transrectal biopsy and a transrectal saturation biopsy (median 27 cores) to accurately select candidates for active surveillance. In their study, which included radical prostatectomy findings to confirm biopsy results, there was no difference in the rate of upgrading between the two approaches.

Transperineal template mapping prostate biopsy has been shown to identify tumors (often anteriorly located) that are missed by transrectal biopsy sampling among men who might be considered suitable for active surveillance (Onik et al, 2009; Ayres et al, 2012; Barzell et al, 2012; Taira et al, 2013). The rate of upgrading on transperineal mapping biopsies is similar to the rate of upgrading in radical prostatectomy specimens in men considered appropriate for surveillance, suggesting that this approach may provide more accurate information for men who are willing to undergo a more invasive procedure. However, at present this approach would not be considered standard practice prior to embarking on surveillance. Some investigators believe that targeting lesions identifiable by mMRI may provide an alternative means of excluding the presence of high-grade cancer among men considering surveillance (Sonn et al, 2014).

Imaging. mMRI has been reported to have high sensitivity and specificity for high-grade prostate cancers and thus could be of value in reducing disease misclassification and selecting and monitoring individuals interested in active surveillance (Hoeks et al, 2014). Diffusion-weighted MRI, or the evaluation of the diffusion of water through tissues, has been shown to correlate indirectly with Gleason score (Vargas et al, 2011) and could provide an improvement in the ability to identify and target for biopsy the higher-grade cancers. Preliminary analyses of small cohorts of men suggest that, as compared to men without suspicious lesions on mMRI, those with suspicious lesions are at substantially greater risk of disease reclassification while on surveillance, including upgrading (Fradet et al, 2010; Margel et al, 2012; Mullins et al, 2013). Turkbey and associates (2013) evaluated men who underwent mMRI and subsequent radical prostatectomy and reported that mMRI had the lowest misclassification rate of prostate cancers that were more than 0.5 mL and/or Gleason pattern 4/5 as compared to other clinical criteria used to select men for active surveillance. In contrast, an evaluation of men who would be considered suitable for active surveillance—based on a 21-core transrectal biopsy, stage,

and PSA level—and who underwent MRI prior to radical prostatectomy demonstrated no benefit of MRI in predicting the presence of extraprostatic (pT3-4) disease or Gleason score 4+3 or higher (Ploussard et al, 2011). Variability in studies evaluating the use of mMRI in the active surveillance setting are likely due to differences in patient selection, mMRI protocols, and image interpretation. Thus the precise role of mMRI in active surveillance has yet to be clearly defined.

Biomarkers. Both serum and urinary biomarkers have been evaluated in active surveillance populations. **Volume-adjusted PSA (PSA density)** has been a consistent independent predictor of disease reclassification (both cancer volume on biopsy and grade) during surveillance (Tseng et al, 2010; Kotb et al, 2011; San Francisco et al, 2011; Cary et al, 2014), after adjusting for other predictors, including mMRI (Vourganti et al, 2012). As compared to surveillance programs that use PSA density as an enrollment criterion, those that do not do so report higher rates of grade reclassification on surveillance biopsies (Han et al, 2012). For example, the rate of grade reclassification was approximately 4% at each biopsy in a program using PSA density as an enrollment criterion (Tosoian et al, 2011) compared to 20% to 30% when PSA density was not used (Porten et al, 2011). Among men who meet strict criteria for surveillance, including a PSA density below 0.15 ng/mL per gram, there is a direct relationship between absolute PSA level and disease reclassification on surveillance (Umbehr et al, 2014). However, no PSA cut point had both high sensitivity and specificity for reclassification, including grade reclassification. In men who do not have Gleason pattern 4-5 at surveillance biopsy on active surveillance but who pass thresholds for volume reclassification (more than two cores positive and/or more than 50% involvement of any core with cancer), over 90% of those with a PSA level below 4 ng/mL have insignificant cancers that would not warrant curative intervention (Han et al, 2012). Thus continued monitoring may be safe for men with low-grade cancer who have absolute PSA levels below 4 ng/mL even when the extent of cancer on biopsy may disqualify them for surveillance using strict selection criteria.

PSA kinetics, specifically PSA doubling time, has been used in some surveillance programs as a trigger for intervention (Dall'Era et al, 2012). In the watchful waiting arm of the SPCG-4 study, both PSA at diagnosis and PSA velocity during the first 2 years of follow-up were associated with the development of lethal prostate cancer (Fall et al, 2007). However, regardless of the PSA velocity cut point, the ability to accurately classify men who did and did not die of prostate cancer was low. While PSA kinetics has been associated with adverse pathology in men on surveillance (Ng et al, 2009), PSA kinetics (velocity or doubling time) has not been consistently associated with disease reclassification (Ross et al, 2010; Whitson et al, 2011; Thomsen et al, 2014).

PSA isoforms (e.g., percentage of fPSA and proPSA) have been shown to be associated with the presence of more aggressive prostate cancer (Carter et al, 1997; Carter, 2012; Guazzoni et al, 2012). Thus it is not surprising that studies have shown a relationship between PSA isoforms and disease reclassification on surveillance. In conjunction with the percentage of cancer involvement in a biopsy tissue core, the percentage of fPSA was indirectly associated with biopsy reclassification in an active surveillance program (Tseng et al, 2010). The risk of biopsy reclassification (including volume and grade) among 321 men enrolled in active surveillance was 7.6% (95% confidence interval [CI] 4.5% to 11.8%) for men with a fPSA above 15% and a maximum percentage of core involvement with cancer less than 35%, compared to 29.2% (95% CI 20.3% to 39.3%) for those with a fPSA of 15% or below and a maximum percentage of core involvement with cancer of 35% or more. In addition, tissue and serum [−2]proPSA (p2PSA) levels were directly associated with the probability of biopsy reclassification and treatment while on surveillance (Makarov et al, 2009; Isharwal et al, 2011). Tosoian and colleagues (2012) evaluated baseline and longitudinal measures of total PSA, fPSA, p2PSA/fPSA, and the Prostate Health Index (PHI), which uses the formula $(p2PSA/fPSA) \times \%total\ PSA$ to evaluate three markers simultaneously. The authors reported that both baseline and longitudinal measures of all of the isoforms

were significantly associated with upgrading at biopsy, whereas total PSA was not. Longitudinal measures appeared to provide increased discrimination for grade reclassification as compared to baseline values. Like the PHI, which relies on the relationship between PSA, fPSA, and p2PSA, a panel of four kallikrein markers (total PSA, fPSA, intact PSA, and human glandular kallikrein or hK2) has been associated with “aggressive” prostate cancer among men with screening-detected cancers undergoing radical prostatectomy (Carlsson et al, 2013). The four-kallikrein panel has not been specifically evaluated in an active surveillance setting.

PCA3 (DD3), a noncoding messenger RNA that can be measured in urine, is overexpressed in prostate cancer (Bussemakers et al, 1999) and has been found to be associated with both the grade and volume of prostate cancer among men undergoing prostatectomy (van Poppel et al, 2012). A urinary assay measuring transcript levels of the fusion between the *TMPRSS2* gene and the *ERG* transcription factor (*TMPRSS2:ERG*) was reported to be directly associated with tumor size and Gleason score at prostatectomy, as well as upgrading of Gleason grade at prostatectomy (Tomlins et al, 2011). However, in an active surveillance population, the addition of the urinary markers PCA3 and *TMPRSS2:ERG* combined did not significantly improve the prediction of Gleason score above 6 as compared to PSA alone (Lin et al, 2013). Marker panels that combine serum and urinary assays may provide improved risk stratification for men considering surveillance but will need further evaluation before application to clinical practice.

KEY POINTS: OBSERVATIONAL STRATEGIES FOR PROSTATE CANCER: WATCHFUL WAITING AND ACTIVE SURVEILLANCE

- Active surveillance has become a standard alternative to curative intervention for select patients diagnosed through PSA-based screening in whom it is judged that the natural history of the disease will be prolonged.
- Most physicians typically monitor a patient on surveillance with PSA and digital rectal examination at least biannually, and perform surveillance prostate biopsies at 1- to 2-year intervals.
- The finding of high-grade disease (Gleason score 7 or higher) on surveillance biopsies has been considered a trigger for intervention in most active surveillance programs.

PATIENT AND DISEASE FACTORS AFFECTING THE CHOICE OF AND ADHERENCE TO ACTIVE SURVEILLANCE

Patient and Physician Perceptions

Treatment decision making for prostate cancer is complex for both patients and physicians, especially when facing multiple options without clear evidence for superiority of any single strategy. The concept of active surveillance for any malignancy poses particular challenges as a diagnosis of “cancer” often evokes many preconceived emotions. **The psychosocial burden of being diagnosed with prostate cancer makes selection of and adherence to active surveillance uniquely challenging.** Patients and partners may experience considerable anxiety, distress, and uncertainty when making prostate cancer treatment decisions, which must be addressed (Pickles et al, 2007).

Davison and Goldenberg (2011) surveyed men on active surveillance and determined that the physician's recommendation has one of the greatest impacts on treatment decision. **Physician attitudes are therefore critical to wider utilization of surveillance for low-risk tumors.** Particularly for younger men, surgery is most often chosen over active surveillance with physicians specifically recommending *against* active surveillance in the majority (75%) of patients (Sidana et al, 2012). Physician perceptions regarding active

surveillance may arise from a general lack of knowledge regarding this treatment approach, concern over how best to safely identify patients and implement active surveillance, and uncertainty over disease progression. As more long-term data regarding the efficacy of active surveillance become available, along with advances in imaging and molecular tumor analyses, many of these perceptions should change.

Studies report considerable variation in patient factors that drive treatment decision making for prostate cancer (Zeliadt et al, 2006). The desire for cancer eradication and preservation of quality of life, however, are predominant and common themes. This drive to completely rid oneself of cancer, however, particularly in younger patients, tends to lead toward aggressive treatment over active surveillance regardless of risk (Penson, 2012; Sidana et al, 2012). Upon specifically questioning men who select active surveillance compared with men selecting other treatments (radiation or surgery), men who choose surveillance cite a desire to avoid potential negative quality-of-life effects of therapy, particularly in regard to sexual functioning, as an important driver of their decision (Volk et al, 2014). Successful active surveillance is perceived by patients to be a well-organized treatment plan and part of an ongoing relationship with the health care provider and is not viewed as a final decision, but possibly the first of a sequence of treatment decisions (Volk et al, 2014). Patients should therefore understand that the goal of surveillance is to identify early signs of progression and that a certain number of men will be recommended for additional therapy over time. An analysis of 768 men with prostate cancer showed that men choosing active surveillance also commonly report a desire to avoid active or invasive treatment as a primary reason (Anandadas et al, 2011). To better understand important factors regarding the selection of surveillance, Goh and colleagues (2012) utilized a telephone-based survey to query men and showed that a better understanding of prostate cancer and less inconsistency in information received seemed to relate with reduced distress regarding patient decision making. A prostate cancer diagnosis carries a substantial psychological burden and it is important for patients to understand the natural history of their specific disease characteristics and the risk their particular cancer may pose before making treatment decisions. **With active surveillance, physicians must facilitate this understanding of the biology of prostate cancer and the likely indolent nature of their particular tumor** (Penson, 2012). Whereas a baseline fear of cancer recurrence is associated with poorer satisfaction with care after prostate cancer treatment, so too are declines in urinary, sexual, and bowel function (Resnick et al, 2013a). If the overriding fear of cancer can be adequately addressed, surveillance offers the ability to preserve function, leading to overall high satisfaction with care. Studies show that contemporary men who successfully adhere to active surveillance understand that their cancers are likely small and slow growing, making immediate treatment unnecessary (Volk et al, 2014). Davison and Goldenberg (2011) found that 55% of men reported low anxiety levels about the cancer progressing while on surveillance, which only comes from a clear understanding of the natural history of the disease.

Patient perceptions and understanding of active surveillance have improved over time (Mishra et al, 2013). This is primarily believed to be due to increased endorsement of active surveillance by national medical organizations along with increased emphasis on preserving quality of life. Analyzing anonymous Internet conversations, Mishra and associates (2013) reported that contemporary conversations emphasized concern over receiving unbiased recommendations from physicians regarding treatment options for prostate cancer. **These comments underscore the importance of a collaborative relationship between patient and physician when embarking on surveillance, which becomes critical for treatment selection and adherence.** Patient partners are often involved in treatment decision making for prostate cancer and therefore are important to be engaged in the physician-patient relationship (Zeliadt et al, 2011).

Future research should focus on developing concise recommendations for wider implementation of active surveillance with strong

consideration of patient and physician perceptions. Physicians must learn to integrate clinical, biologic, and likely image-based variables for careful risk assessment and how to adequately communicate these with patients. Research efforts will also need to focus on identifying interventions aimed at improving quality of life and treatment adherence while on surveillance, including coping mechanisms and spousal/partner support. The NIH consensus statement outlines more specific future research needs for prostate cancer survivorship particularly for men on active surveillance (Ganz et al, 2012).

Selection Criteria

The decision to manage prostate cancer with surveillance is based on both patient and disease factors. Diagnostic clinical characteristics are used to initially estimate disease risk and to determine which patients may be eligible for active surveillance. Certain tumor characteristics may pose different risks for different patients after consideration of age and performance status. While there are no level 1 data that determine the optimal selection criteria, it is generally accepted that men with low-risk, localized disease are the best candidates. Eligibility characteristics described from the experiences of several large published cohorts are presented in Table 113-3. Physicians and patients must decide which criteria are best for their particular practice patterns, and while different criteria may predict certain outcomes (i.e., pathologic, disease reclassification, treatment-free survival), none has been directly validated to predict disease-specific or overall survival. Once candidates are identified, the decision to proceed with active surveillance is based on careful discussion between physician and patient considering the patient's interest in and willingness to adhere to the recommended surveillance protocol.

The Epstein criteria were selected to identify potentially low-risk tumors and are among the most popular used for patient selection for active surveillance. By these criteria, "insignificant" tumors are predicted by clinical Gleason pattern 3 or less, clinical stage T1c and either (1) PSA density 0.1 ng/mL per gram or less, two or fewer positive biopsy cores, and no cores with greater than 50% involvement or (2) PSA density of 0.15 ng/mL per gram or less and cancer smaller than 3 mm on only one biopsy core. The NCCN now recommends active surveillance as primary treatment for men with "very" low-risk prostate cancer defined by PSA level 10 ng/mL or less, clinical stage T2a or less, Gleason grade 3+3 or less, PSA density 0.15 ng/mL per gram or less, two or fewer cores positive, and any single-core positivity 50% or less. The NCCN guidelines recommend offering the option of active surveillance for men presenting with low-risk disease defined as PSA level 10 ng/mL or less, clinical stage T2a or less, and Gleason grade 3+3 or less. The American and European Urologic Associations have similarly published guidelines for offering active surveillance for men with prostate cancer. Patient factors such as age, comorbid illness, and willingness to adhere to surveillance strategies must also be considered during patient selection.

More stringent criteria for offering active surveillance will reduce the number of candidates for this approach, and although some series describe results of surveying men with higher Gleason score tumors (3+4), these data must be interpreted cautiously (Ng et al, 2009; van den Bergh et al, 2009b; Klotz et al, 2010; Cooperberg et al, 2011). While more strict criteria may reduce the risks of disease misclassification, this further limits potential candidates. Because up to 33% of men with presumed low-risk disease may be incorrectly classified at diagnosis, a confirmatory prostate biopsy serves to reduce this risk (Iremashvili et al, 2012a).

Surveillance Strategies

As with selection criteria, there is no overall consensus on the optimal strategies for surveillance. Ongoing prospective studies integrating novel imaging and molecular analyses will allow for more personalized risk assessment and recommendations for surveillance. Currently, because tumor grade is the best predictor of

TABLE 113-3 Selection Criteria and Outcomes from Published Active Surveillance Series

PSA, prostate-specific antigen.

cancer biology, repeat prostate biopsies over time are the cornerstone of active surveillance. Early “confirmatory” biopsy serves to limit the risk of clinical undergrading resulting from sampling, estimated from surgical series to range from 20% to 30% on a typical 12-core transrectal biopsy (Conti et al, 2009; Smaldone et al, 2010; Suardi et al, 2010). Many clinicians therefore advocate for this repeat biopsy within 3 to 6 months of diagnosis. The pathologic outcomes after the first repeat biopsy are well described, with Gleason grade changes and thus risk reclassification occurring 2.5% to 28% of the time. These numbers are sensitive to selection criteria and biopsy technique. **The critical role of repeat prostate biopsy for successful identification of higher-risk disease during surveillance cannot be overemphasized.** When describing characteristics of two men presenting with low-risk features who subsequently died from prostate cancer after a period of surveillance within the Royal Marsden cohort, it was noted that both men were found to have higher-grade disease (Gleason 8 and 9) on first repeat biopsy 13 and 24 months after diagnosis, respectively (Selvadurai et al, 2013). Both patients were also found to have substantial tumor burdens on MRI.

Serial prostate biopsies are then variably performed from an annual basis to once every 3 to 4 years. Men within the Johns Hopkins cohort undergo yearly biopsies while the University of Toronto advocates for an initial confirmatory biopsy after 6 to 12 months and then every 3 to 4 years (Klotz, 2012). The risk of disease reclassification continues over time while on surveillance, likely a result of both undersampling and true histologic disease progression in either tumor grade or volume. Within the University of California, San Francisco (UCSF) cohort, the risk of grade progression to Gleason 3+4 or greater ranged from 22% to 30% with each surveillance biopsy (Cary et al, 2014). With a median follow-up of 5.7 years in the Royal Marsden series, the rates of adverse histology

(defined as ≥Gleason 4+4 or percent positive cores ≥50) at 2 and 5 years were 6% and 22%, respectively (Selvadurai et al, 2013).

Psychosocial Aspects

The common emotions of uncertainty and anxiety surrounding treatment decisions for prostate cancer also affect patient adherence to active surveillance protocols. Within a large cohort series of active surveillance, up to 13% of men ultimately received other treatments in the absence of clinical reclassification or progression, demonstrating how psychosocial factors may drive unwillingness to continue with surveillance (Dall’Era et al, 2008). Men on surveillance have unique and specific survivorship needs, which are important to address to maintain quality of life and avoid psychological distress over time. Identifying and describing these needs is important for implementing interventions aimed at improving adherence to active surveillance. Patient anxiety over time has been studied within the Prostate Cancer Research International: Active Surveillance (PRIAS) study (van den Bergh et al, 2010). Within this cohort, overall patient-reported anxiety and uncertainty regarding treatment decisions were generally lower than reported for other treatments for prostate cancer. Additionally, the authors noted that over time anxiety remained steady, suggesting that within an organized framework of careful monitoring patients fare well psychologically (van den Bergh et al, 2009a, 2010). The authors also identified that patients with a more neurotic personality tended to not tolerate surveillance as well as other patients. Better overall physical health, however, correlated with lower anxiety and distress (van den Bergh et al, 2010). **Because most men with prostate cancer will experience non-prostate-cancer-related mortality, this underscores the importance of implementing general physical and mental health improvement measures for men on surveillance.** The Prostate

Cancer Lifestyle Trial examined the role of lifestyle modifications and found that exercise and attention to stress management can improve treatment-free survival for men on surveillance (Frattaroli et al, 2008). Additional data from this trial suggest that comprehensive lifestyle changes can also affect prostate cancer gene expression and telomere length, therefore having positive impacts on both biologic and psychosocial factors (Ornish et al, 2008, 2013).

KEY POINTS: PATIENT AND DISEASE FACTORS AFFECTING THE CHOICE OF AND ADHERENCE TO ACTIVE SURVEILLANCE

- The psychosocial burden of being diagnosed with prostate cancer makes selection of and adherence to active surveillance uniquely challenging.
- Physician attitudes are critical to wider utilization of surveillance for low-risk tumors.
- Early “confirmatory” biopsy serves to limit the risk of clinical undergrading resulting from sampling, estimated from surgical series to range from 20% to 30% on a typical 12-core transrectal biopsy.

COMPARATIVE OUTCOMES OF TREATMENT AND OBSERVATIONAL STRATEGIES

Treatment-Free, Disease-Specific, and Overall Survival

Although studies have been completed directly comparing radical prostatectomy with watchful waiting, to date no prospective, randomized data exist comparing active surveillance with immediate treatment. Table 113-3 depicts the reported outcomes from contemporary active surveillance series, which can be used to counsel patients for this treatment approach. Disease-specific and all-cause

survival over the periods of study have been reportedly high and compare favorably with longer-term outcomes after prostatectomy or various forms of radiotherapy in similar-risk men (Cooperberg et al, 2010b; Eggener et al, 2011). In an effort to better estimate the excess risk of prostate cancer mortality with active surveillance versus immediate treatment, Xia and associates (2012) developed a simulation model for a hypothetical cohort of men ages 40 to 90 years with low-risk disease. With several assumptions inherent to modeling, the authors calculated an average increase in life expectancy of only 1.8 months with immediate treatment while men on surveillance remained free of treatment for an additional 6.4 years. Because measures of disease progression or reclassification are sensitive to entry criteria and variable definitions, treatment-free survival has emerged as another comparative relevant end point for surveillance and is depicted in Table 113-3 for selected studies. Figure 113-2 shows the estimated treatment-free survival and freedom from disease risk reclassification based on repeat biopsy characteristics from the Johns Hopkins cohort. When interpreting results from published series, careful consideration must be given to clinical characteristics at study entry, surveillance strategies, definitions of disease progression, and indications for secondary therapy.

Investigators from Johns Hopkins University have prospectively treated men with active surveillance for suspected low-risk prostate cancer, defined by Gleason score 6 or less, clinical stage T1c or less, PSA density 0.15 ng/mL per gram or less, two or fewer positive biopsy cores, and 50% or less single-core involvement (Tosoian et al, 2011). This study reported no deaths attributable to prostate cancer and no cases of metastatic disease after a median follow-up of 2.7 years (Tosoian et al, 2011). In this group, patients are surveyed with yearly prostate biopsy and, in over 600 men, 213 (33%) were risk reclassified based on histologic parameters (Gleason score or tumor volume) over time (Umbehr et al, 2014).

In a cohort of 450 low- and intermediate-risk men from Toronto, Canada with the longest median follow-up of 6.8 years, Klotz (2012) reported a 10-year overall survival of 68% with only 5 reported prostate cancer-specific deaths. A confirmatory biopsy was

Figure 113-2. Estimated biopsy reclassification and treatment-free survival for men on active surveillance from the Johns Hopkins cohort. (Modified from Tosoian JJ, Trock BJ, Landis P, et al. Active surveillance program for prostate cancer: an update of the Johns Hopkins experience. J Clin Oncol 2011;29:2185–90.)

performed 6 to 12 months after the initial diagnosis and then every 3 to 4 years. Three of the five patients who died from prostate cancer underwent radical therapy and all five demonstrated a rapid PSA doubling time of less than 2 years.

The PRIAS study was initiated in 2006 and collects data on men treated with active surveillance in over 100 medical centers from 17 countries (Bul et al, 2013). With a median follow-up of 1.6 years and 2495 men, the study reported 75.6% treatment-free survival with no prostate cancer-specific deaths. Although still a very early series, this relatively large, multinational cohort is expected to contribute important data on this management strategy in the future.

Outcomes for African-American men on active surveillance have been reported and may differ from those for Caucasian men. The added risk of race to prostate cancer diagnosis and outcomes is well known and is important to consider when applying these data regarding active surveillance specifically to African-American men. **In a multivariate analysis of predictors for progression on repeat biopsy in an active surveillance cohort, African-American men were noted to have an independent increased risk for progression over their Caucasian counterparts (Iremashvili et al, 2012b).** In a separate cohort of men on active surveillance, African-American men were noted to have lower treatment-free survival (66%) than non-African-Americans (82%) after a median of 34 months (Odom et al, 2014). On multivariate analysis, African-American men were more likely to progress (odds ratio [OR] 4.46, 95% CI 1.52 to 13.10) and undergo treatment (OR 2.29, 95% CI 1.03 to 5.08).

Identifying other baseline predictors of risk reclassification and need for treatment may ultimately improve patient counseling and tailor surveillance strategies for men with prostate cancer. In a group of 465 men on surveillance at UCSE, negative confirmatory biopsy and lower PSA density were associated with lower rates of progression (Cary et al, 2014). **Analyzing the ability of selection criteria to predict pathology within a surgical cohort, Reese and colleagues (2013) demonstrated that PSA density greater than 0.15 ng/mL per gram and Gleason score of 3+4 were associated with adverse pathologic findings, suggesting that these factors may be more significant than biopsy positive core number or estimates of tumor percentage within each core.** The significant relationship between PSA density (≥ 0.15 ng/mL per gram) and adverse pathologic features at prostatectomy was also reported within the PRIAS group of men (Bul et al, 2013).

Outcomes after Secondary Treatment for Progression

While both watchful waiting and active surveillance offer treatment for progressive disease, the timing and approaches differ. Watchful waiting generally utilizes androgen deprivation therapy for symptomatic, metastatic progression while surveillance offers the opportunity to administer curative therapy for higher-risk, localized disease. A subset of patients also elect to undergo secondary treatment in the absence of clinical changes. Analyzing and understanding the outcomes of men who receive further treatment, particularly after a period of surveillance, is important for counseling men regarding the risks and expectations of this approach to managing prostate cancer.

In 192 men from the Johns Hopkins cohort who underwent delayed prostatectomy or radiotherapy, 9.4% experienced biochemical recurrence with a median follow-up of 2 years after delayed prostatectomy and 2.8 years after radiation (Tosoian et al, 2011). No men developed metastatic disease or died from prostate cancer. After radical prostatectomy, the majority of men (65%) had organ-confined disease and 27% of men had indolent disease (dominant nodule < 0.5 mL in size and no Gleason pattern 4 or 5). One patient had lymph node involvement at the time of surgery and one patient had seminal vesicle invasion (Duffield et al, 2009).

Investigators from the University of Toronto reported outcomes for 125 men treated with either prostatectomy (35 men) or radiotherapy (90 men) for curative intent after a period of surveillance (Klotz, 2012). Overall, higher rates of PSA failure (50.4%) after delayed treatment were reported for this series compared with others. Five-year biochemical recurrence-free survival after prosta-

tectomy was 62% versus 43% after radiotherapy. These figures must be interpreted with consideration of the higher disease risk of this cohort compared with that at Johns Hopkins. Of 36 treated men who presented with intermediate-risk disease, only one progressed to metastatic disease and death (Klotz, 2012).

Comparative pathologic outcomes for men undergoing immediate versus delayed prostatectomy after a period of surveillance can be studied, but must be interpreted cautiously. Compared with a group of similar-risk men undergoing immediate surgery, Dall'Era and associates (2011) reported no differences in rates of extraprostatic extension or positive margins for men undergoing surgery after a median of 18 months of surveillance. In a similar report from Johns Hopkins, rates of "noncurable" prostate cancer after delayed prostatectomy were low (23%) and did not differ from those of men undergoing immediate surgery (Warlick et al, 2006). Of 27 men from the PRIAS study undergoing radical prostatectomy after progression, 17% had evidence of pT3a disease on final pathology and 38% had positive surgical margins (Bul et al, 2013). Most men from these studies were treated with evidence of pathologic reclassification on surveillance needle biopsy and therefore must be compared to similar-risk men undergoing immediate surgery. **The majority of men classified as low risk at diagnosis remain untreated on surveillance.**

KEY POINTS: COMPARATIVE OUTCOMES OF TREATMENT AND OBSERVATIONAL STRATEGIES

- Disease-specific and all-cause survival from published active surveillance series have been high and compare favorably with longer-term outcomes after prostatectomy or various forms of radiotherapy in similar-risk men.
- The outcomes of men undergoing delayed radical prostatectomy or radiation therapy after a period of active surveillance appear similar to men treated immediately after diagnosis.

FUTURE RESEARCH NEEDS

Improvements in prostate imaging, biomarker discovery, and genetic profiling of prostate cancers will very likely change the approach to management of men diagnosed with localized prostate cancer. Currently, active surveillance is underutilized in part because of the dual concerns that a cancer has been misclassified on a prostate biopsy and the inability to define biologically which cancers have an aggressive phenotype. Thus there is both overtreatment of indolent disease and undertreatment of aggressive disease. mMRI, including diffusion-weighted imaging, magnetic resonance spectroscopy, and contrast-enhanced sequences, is being studied extensively for prostate cancer, and the role this plays in patient selection and surveillance strategies will soon be defined. Studies utilizing novel imaging modalities such as ^{18}F -sodium fluoride and ^{11}C -choline positron emission tomography are producing exciting data in prostate cancer and may one day play a role in surveillance of low-risk tumors (Scattoni et al, 2007; Jadvar et al, 2012).

Two gene expression assays are now commercially available for prostate cancer and are integrated with baseline clinical variables to provide more precise risk assessment for patients. The Oncotype DX® assay (Genomic Health, Inc., Redwood City, CA) measures expression levels of 17 specific genes within four molecular pathways and was designed to predict the risk of adverse pathology for men with NCCN very low-, low-, or intermediate-risk prostate cancer (Knezevic et al, 2013). The Prolaris® assay (Myriad Genetics, Inc., Salt Lake City, UT) measures 31 genes involved in cell cycle progression to predict disease progression and prostate cancer-specific mortality (Cuzick et al, 2011; Cooperberg et al, 2013). It is unclear how these gene expression assays will perform and, with reported ORs in the range of 1.5 to 3 for predicting low-risk disease, accurate classification may be poor (Pepe et al, 2004). Ongoing validation studies and head-to-head comparisons will better define

the role of these molecular tests in early-stage prostate cancer and how they will enhance treatment decision making.

In the future it is likely that men with newly diagnosed localized prostate cancer will have had an assessment of the prostate using mMRI, targeted biopsies of lesions considered suspicious, and gene expression signatures that focus on profiling the cancer based on molecular pathways associated with aggressiveness (Cooperberg et al, 2013; Donovan and Cordon-Cardo, 2013; Haffner et al, 2013; Liu et al, 2013). Together with serum and urine biomarkers, this new paradigm may enhance our current stratification systems that rely to a great extent on light microscopic grading. This multidimensional approach may improve the ability to select the most appropriate candidates for surveillance, as well as our ability to longitudinally monitor specific lesions within the prostate for evidence of disease progression.

Complications

Surgical Modifications to Classic Anatomic Radical Prostatectomy

Salvage Radical Prostatectomy

Summary of Radical Retropubic Prostatectomy

Radical Perineal Prostatectomy

There is no better way to cure cancer that is confined to the prostate than total surgical removal. Radical prostatectomy is the only form of treatment for localized prostate cancer that has been shown in a randomized controlled trial to reduce progression to metastases and death from the disease (Holmberg et al, 2002; Bill-Axelson et al, 2008). Furthermore, on the basis of improved understanding of the periprostatic anatomy, today less bleeding and improved rates of postoperative continence and potency are seen (Walsh, 1998, 2000; Nielsen et al, 2008).

Technically, radical retropubic prostatectomy (RRP) is one of the most difficult operations in the field of urology. The three goals of surgery, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function. Great skill and experience in the selection of surgical candidates and operative technique are necessary to achieve all three. This chapter summarizes our experience, with the hope that it will shorten the reader's learning curve. A video demonstrating a detailed description of the surgical technique is also available (Walsh and Garcia, 2004).

RADICAL RETROPUBIC PROSTATECTOMY: SURGICAL ANATOMY

Venous and Arterial Anatomy

The veins of the prostate drain into the Santorini plexus. It is necessary to have a complete understanding of these veins to avoid excessive bleeding and to ensure a bloodless field in exposing the membranous urethra and the apex of the prostate. The deep dorsal vein leaves the penis under the Buck fascia between the corpora cavernosa and penetrates the urogenital diaphragm, dividing into three major branches: the superficial branch and the right and left lateral venous plexuses (Reiner and Walsh, 1979) (Fig. 114-1). The superficial branch, which travels between the puboprostatic ligaments, is the centrally located vein overlying the bladder neck and prostate. This vein is easily visualized early in retropubic operations and has communicating branches over the bladder itself and into the endopelvic fascia. The superficial branch lies outside the anterior prostatic fascia.

The common trunk and lateral venous plexuses are covered and concealed by the prostatic and endopelvic fascia. The lateral venous plexuses traverse posterolaterally and communicate freely with the pudendal, obturator, and vesical plexuses. Near the puboprostatic ligaments, small branches from the lateral plexus often penetrate the pelvic sidewall musculature and communicate with the internal pudendal vein. The lateral plexus interconnects with other venous systems to form the inferior vesical vein, which empties into the internal iliac vein. With the complex of veins and plexuses anasto-

mosing freely, any laceration of these friable structures can lead to considerable blood loss.

The prostate receives arterial blood supply from the inferior vesical artery. According to Flocks (1937), after the inferior vesical artery provides small branches to the seminal vesicle and the base of the bladder and prostate, the artery terminates in two large groups of prostatic vessels: the urethral and capsular groups (Fig. 114-2). The urethral vessels enter the prostate at the posterolateral vesicoprostatic junction and supply the vesical neck and periurethral portion of the gland. The capsular branches run along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. The capsular vessels terminate as a small cluster of vessels that supply the pelvic floor. On histologic examination, the capsular arteries and veins are surrounded by an extensive network of nerves (Walsh and Donker, 1982; Walsh et al, 1983; Lue et al, 1984; Lepor et al, 1985). These capsular vessels provide the macroscopic landmark to aid in the identification of the microscopic branches of the pelvic plexus that innervate the corpora cavernosa.

The major arterial supply to the corpora cavernosa is derived from the internal pudendal artery. However, pudendal arteries can arise from the obturator, inferior vesical, and superior vesical arteries. Because these aberrant branches travel along the lower part of the bladder and anterolateral surface of the prostate, they are divided during radical prostatectomy. This may compromise arterial supply to the penis, especially in older patients with borderline penile blood flow (Breza et al, 1989; Polascik and Walsh, 1995; Rogers et al, 2004).

Pelvic Plexus

The autonomic innervation of the pelvic organs and external genitalia arises from the pelvic plexus, which is formed by parasympathetic, visceral, efferent, preganglionic fibers that arise from the sacral center (S2 to S4), and sympathetic fibers via the hypogastric nerve from the thoracolumbar center (Walsh and Donker, 1982; Lue et al, 1984; Lepor et al, 1985; Schlegel and Walsh, 1987; Walsh, 2007) (see Fig. 114-1). The pelvic plexus in men is located retroperitoneally beside the rectum 5 to 11 cm from the anal verge and forms a fenestrated rectangular plate that is in the sagittal plane with its midpoint at the level of the tip of the seminal vesicle.

The branches of the inferior vesical artery and vein that supply the bladder and prostate perforate the pelvic plexus. For this reason, ligation of the so-called lateral pedicle in its midportion not only interrupts the vessels but also transects the nerve supply to the

Figure 114-1. Location of the superficial and deep branches of the dorsal vein as they travel over the anterior and anterolateral surfaces of the prostate. Note the common trunk located immediately over the urethra. This is the site where the dorsal vein is transected. The pelvic plexus: The autonomic innervation of the pelvic organs arises from the pelvic plexus, which is formed by parasympathetic fibers that arise from the sacral center (S2 to S4) and sympathetic fibers via the hypogastric nerve from the thoracolumbar center. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. The branches that innervate the corpora cavernosa enter in a spraylike distribution 20 to 30 mm distal to the junction of the prostate and bladder, where they continue distally posterolateral to the prostate. n., nerve. (© Brady Urological Institute.)

Figure 114-2. Arterial supply to the prostate. The inferior vesical artery terminates in two large groups of vessels. One group, the urethral vessels, enters the prostate at the posterolateral vesicoprostatic junction to supply the bladder neck and periurethral portions of the gland. The second group, the capsular branches, runs along the pelvic sidewall in the lateral pelvic fascia posterolateral to the prostate, providing branches that course ventrally and dorsally to supply the outer portion of the prostate. These capsular arteries and veins are intimately associated with the branches of the pelvic plexus forming the neurovascular bundle (NVB), which is used as the macroscopic landmark to aid in the identification of the microscopic branches of these nerves. Note at the apex that small branches of the nerves travel anteriorly away from the vessels. a., artery; inf., inferior; v., vein. (© Brady Urological Institute.)

Figure 114-3. The striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. The dorsal vein complex travels through the sphincter complex. (© Brady Urological Institute.)

prostate, urethra, and corpora cavernosa. The pelvic plexus provides visceral branches that innervate the bladder, ureter, seminal vesicles, prostate, rectum, membranous urethra, and corpora cavernosa. In addition, branches that contain somatic motor axons travel through the pelvic plexus to supply the levator ani, coccygeus, and striated urethral musculature. The nerves innervating the prostate travel outside the capsule of the prostate and Denonvilliers fascia until they perforate the capsule where they enter the prostate.

The branches to the membranous urethra and corpora cavernosa also travel outside the prostatic capsule in the lateral pelvic fascia dorsolaterally between the prostate and rectum (see Fig. 114-1). Although these nerves are microscopic, their anatomic location can be estimated intraoperatively by use of the capsular vessels as a landmark. This structure, which is referred to here as the neurovascular bundle (NVB), has been termed the *NVB of Walsh* (Stedman's Medical Dictionary, 2000) (see Fig. 114-2). As emphasized by Takenaka and colleagues (2004) and Costello and colleagues (2004), the cavernous branches join the capsular arteries and veins in a spraylike distribution to form the NVB 20 to 30 mm distal to the junction of the bladder and prostate (see Fig. 114-2). The NVBs are located in the lateral pelvic fascia between the prostatic fascia and the levator fascia. At the apex of the prostate, the branches of the nerves to the cavernous bodies and striated sphincter also have a spraylike distribution both anteriorly and posteriorly with wide variation (Costello et al, 2004; Takenaka et al, 2005). After piercing the urogenital diaphragm, the nerve branches pass behind the dorsal penile artery and dorsal penile nerve before entering the corpora cavernosa (Walsh and Donker, 1982).

Striated Urethral Sphincter

The external sphincter, at the level of the membranous urethra, is often depicted as a "sandwich" of muscles in the horizontal plane. However, Oelrich (1980) demonstrated clearly that the striated urethral sphincter with its surrounding fascia is a vertically oriented tubular sheath that surrounds the membranous urethra. In utero, this sphincter extends without interruption from the bladder to the perineal membrane. As the prostate develops from the urethra, it invades and thins the sphincter muscle, causing a reduction or atrophy of some of the muscle (Fig. 114-3).

In the adult the fibers at the apex of the prostate are horseshoe shaped and form a tubular, striated sphincter surrounding the membranous urethra. Near the apex of the prostate, the edges fuse in the midline posteriorly (Fig. 114-4A). Thus, as Myers (1987) has shown, the prostate does not rest on a flat, transverse

Figure 114-4. A, A cross section through the apex of the prostate demonstrating the relationship among the fascia surrounding the striated sphincter and smooth muscle of the urethra. Note that at this level, the striated sphincter circumferentially surrounds the urethra. Note that the neurovascular bundles (NVBs) are posterolateral to the circumferential striated sphincter. B, A cross section through the midportion of the prostate demonstrating the relationship between the levator fascia, Denonvilliers fascia, and prostatic fascia. Note that the NVBs are located between the layers of the levator fascia and prostatic fascia. In performing a proper nerve-sparing operation, the prostatic fascia must remain on the prostate. (© Brady Urological Institute.)

urogenital diaphragm like an apple on a shelf, with no striated muscle proximal to the apex. Rather, the external striated sphincter is more tubular and has broad attachments over the fascia of the prostate near the apex. This has important implications in the apical dissection and reconstruction of the urethra for preservation of urinary control postoperatively (Walsh et al, 1990).

The striated sphincter contains fatigue-resistant, slow-twitch fibers that are responsible for passive urinary control. Active continence is achieved by voluntary contraction of the levator ani musculature, which surrounds the apex of the prostate and membranous urethra. Some fibers of the levator ani (levator urethrae, pubourethralis) surround the proximal urethra and the apex of the prostate and insert into the perineal body in the midline posteriorly (Myers, 1991, 1994). The pudendal nerve provides the major nerve supply to the striated sphincter and levator ani. When patients are instructed to perform sphincter exercises postoperatively, they are actually contracting the levator ani musculature. However, because the striated urethral sphincter has similar innervation, patients are exercising this important muscle as well. Somatic motor nerves traveling through the pelvic plexus provide additional innervation to the pelvic floor musculature (Zvara et al, 1994; Costello et al, 2004; Takenaka et al, 2005).

Pelvic Fascia

The prostate is covered with three distinct and separate fascial layers: Denonvilliers fascia, the prostatic fascia (also called the *capsule of the prostate*), and the levator fascia. Denonvilliers fascia is a filmy, delicate layer of connective tissue located between the anterior walls of the rectum and prostate (see Fig. 114-4B). This

fascial layer extends cranially to cover the posterior surface of the seminal vesicles and lies snugly against the posterior prostatic capsule. This fascia is most prominent and dense near the base of the prostate and the seminal vesicles and thins dramatically as it extends caudally to its termination at the striated urethral sphincter. On microscopic examination, it is impossible to discern posterior and anterior layers of this fascia (Jewett et al, 1972). For this reason, one must excise this fascia completely to obtain an adequate surgical margin.

In addition to Denonvilliers fascia, the prostate is also invested with the prostatic fascia and levator fascia. Anteriorly and anterolaterally, the prostatic fascia is in direct continuity with the parenchyma of the prostate. The major tributaries of the dorsal vein of the penis and Santorini plexus travel within the anterior prostatic fascia. Laterally, the prostatic fascia fuses with the levator fascia, which covers the pelvic musculature, to form the lateral pelvic fascia (Fig. 114-5) (Myers, 1991, 1994). Posterolaterally, the levator fascia separates from the prostate to travel immediately adjacent to the pelvic musculature surrounding the rectum. The prostate receives its blood supply and autonomic innervation between the layers of the levator fascia and prostatic fascia (see Figs. 114-4B and 114-5).

In an effort to avoid injury to the dorsal vein of the penis and Santorini plexus during radical perineal prostatectomy, the lateral and anterior pelvic fasciae are reflected off the prostate. This accounts for the reduced blood loss associated with radical perineal prostatectomy. In performing RRP, the prostate is approached from outside these fascial investments. For this reason, the dorsal vein complex must be ligated and the lateral pelvic fascia must be divided (Walsh et al, 1983).

Figure 114-5. A lateral view illustrating that the prostate receives its blood supply and autonomic innervation between the layers of the levator fascia and prostatic fascia. a., artery; inf., inferior; NVB, neurovascular bundle; v., vein. (© Brady Urological Institute.)

SURGICAL TECHNIQUE

Preoperative Preparation

The preoperative assessment must include a focused review of systems; a complete medical, surgical, and anesthesia history; an inquiry of all prescription and nonprescription medications; a physical examination; and routine preoperative laboratory testing. Life-threatening complications associated with RRP are rare and include myocardial infarction, cerebrovascular accident (stroke), cardiac arrhythmias, pulmonary embolus, hemorrhage, and anesthesia reactions. The preoperative assessment must identify candidates who are at increased risk for these mortality events to intervene to attenuate these risks.

The preoperative assessment should identify factors that may add to the technical challenge of the surgical procedure, including prior abdominal or pelvic surgery and irradiation, prior transurethral surgery, extensive prostate biopsies, history of significant inflammatory bowel disease, prior use of mesh during inguinal or incisional hernia repairs, and the size of the prostate. Although none of these factors are contraindications for RRP, a greater level of skill and experience may be required to minimize complications.

The observation that up to 15% to 20% of men develop an inguinal hernia after RRP implied that this surgical procedure directly predisposes to the development of hernias (Regan, 1996; Lodding, 2001; Nielsen and Walsh, 2005). Approximately 15% of men undergoing radical prostatectomy will have a coexisting inguinal hernia detected if an appropriate inguinal examination is performed (Lepor and Robbins, 2007). In most of these cases, the inguinal hernias are asymptomatic. These observations suggest that an RRP may transform an asymptomatic inguinal hernia into a symptomatic hernia. Therefore examination of the inguinal canal with Valsalva should be performed, enabling properitoneal hernia repairs at the time of the radical prostatectomy.

Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate. This delay enables inflammatory adhesions or hematomas to resolve so that the anatomic relationships between the prostate and the surrounding structures return to a nearly normal state before surgery. This is especially important if one hopes to preserve the NVBs intraoperatively and avoid rectal injury.

Donation of autologous blood is not performed at our institutions because transfusion rates are under 1%. Erythrocyte-stimulating proteins, which are not approved by the U.S. Food and Drug Administration, have been shown to raise the hematocrit on average percentage points, diminishing postprostatectomy anemia

(Rosenblum et al, 2000). The relatively higher discharge hematocrit attributable to the use of erythrocyte-stimulating proteins affects the pace of recovery because postoperative hematocrit has been shown to influence both time to work and return to activities (Sultan et al, 2006).

The American Urological Association recently published best practice guidelines for the use of prophylactic antibiotics for urologic surgical procedures (Wolf et al, 2008). The recommended prophylactic regimens for open or laparoscopic surgery involving entry into the urinary tract are a first- or second-generation cephalosporin or an aminoglycoside in combination with metronidazole or clindamycin. The duration of therapy should be no longer than 24 hours. We routinely use a first-generation cephalosporin alone and have an infection rate much less than 1%.

The preoperative management of anticoagulants and antiplatelet agents used for the treatment of specific medical conditions, such as prosthetic valves, atrial fibrillation, and coronary artery stent implants, should be performed in conjunction with the internist or cardiologist. With nearly 1 million coronary interventions occurring every year and the majority including an implant of a drug-eluting stent, managing prescribed antiplatelet therapy can create a dilemma balancing the risk for stent stenosis and perioperative bleeding. In the majority of cases, stent thrombosis is a catastrophic event resulting in life-threatening complications (Cutlip et al, 2001). A reasonable compromise for men with drug-eluting stents undergoing RRP is to preoperatively discontinue the thienopyridine while continuing aspirin therapy and restarting the thienopyridine as soon as clinically indicated (Grines et al, 2007).

Patients are prescribed a clear liquid diet on the day before surgery, are requested to drink half a bottle of magnesium citrate in the evening, and have an enema on the morning of surgery. They are admitted to the hospital on that day.

Special Instruments

RRP requires few special instruments. A fiberoptic headlight is essential because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. A standard Balfour retractor with both narrow and wide malleable blades is useful during lymph node dissection and is necessary during radical prostatectomy to provide cranial and posterior retraction on the peritoneum and bladder. Coagulating forceps; small, fine, and regular right-angled clamps; Metzenbaum and Jamison scissors; and 2.5- to 4.5-power loupes are the only other specialized instruments that should be available.

Anesthesia, Incision, and Lymphadenectomy

General endotracheal anesthesia is the preferred anesthesia. The anesthesiologist is encouraged to maintain relative hypotension with systolic blood pressure of no more than 100 mm Hg and to limit the replacement of crystalloid to 1500 mL until the prostate is removed (Davies et al, 2004). The patient is placed in the supine position. The table can be flexed in obese men to increase the distance between the umbilicus and pubis.

The skin is prepared and draped in the usual way. A No. 16 Silastic Foley catheter is passed into the bladder, inflated with 20 mL of saline, and connected to sterile, closed, continuous drainage. The use of a 16-Fr catheter facilitates placement of sutures in the mucosa of the urethra. A right-handed surgeon always stands on the left side of the patient.

An extraperitoneal, lower abdominal incision is made extending from the pubis toward the umbilicus. The anterior fascia is incised down to the pubis, the rectus muscles are separated in the midline, and the transversalis fascia is opened sharply to expose the Retzius space. Laterally, the peritoneum is mobilized off the external iliac vessels to the bifurcation of the common iliac artery. Care is taken to preserve the soft tissue covering the external iliac artery that contains the lymphatics draining the lower extremity. Interruption of these lymphatics may lead to lower extremity edema and lymphocele formation. This maneuver is accomplished

Figure 114-6. View of the right pelvis after completion of the staging pelvic lymph node dissection. Note that the fibroadipose tissue overlying the external iliac artery has not been disturbed and that the obturator nerve, obturator vessels, and hypogastric veins (vv.) over the pelvic floor have been skeletonized. a., artery; n., nerve. (© Brady Urological Institute.)

without dividing the vas deferens. Next, a self-retaining Balfour retractor is placed. Exposure for the lymph node dissection is facilitated by placement of a narrow, malleable blade attached to the Balfour retractor beneath the mobilized vas deferens to displace the peritoneum superiorly and a deep Deaver retractor to retract the bladder medially. Previously, when the vas deferens was routinely divided, some patients complained of persistent testicular pain that the authors attributed to excessive traction on the spermatic cord during this maneuver. However, if the vas deferens is not divided, the traction on the spermatic cord is absorbed by the vas deferens and persistent testalgia is rare.

Pelvic lymph node dissection is performed before the radical prostatectomy. The dissection is initiated on the ipsilateral side of the major tumor in the prostate by dividing the adventitia over the external iliac vein (Fig. 114-6). The lymphatics overlying the external iliac artery are preserved. The dissection proceeds beneath the external iliac vein out to the pelvic sidewall and then inferiorly to the femoral canal, where the lymphatic channels are ligated at a convenient point. There is no need to remove the Cloquet node. The dissection then proceeds cranially along the pelvic sidewall to the bifurcation of the common iliac artery, where the lymph nodes in the angle between the external iliac and hypogastric arteries are removed. Next, the obturator lymph nodes are removed with care to avoid injury to the obturator nerve. The obturator artery and vein are skeletonized but usually are left undisturbed and not ligated unless excessive bleeding occurs. The dissection then continues down to the pelvic floor, exposing the hypogastric veins. This extended dissection removes more lymph nodes than in a more limited dissection, improving staging and providing potential therapeutic benefit in some patients (Allaf et al, 2004; Palapattu et al, 2004). A similar procedure is performed on the opposite side. If the patient has a well-differentiated to moderately well-differentiated tumor (Gleason grade < 8) and the lymph nodes are normal to palpation, frozen-section analysis is not performed (Sgrignoli et al, 1994; Cadeddu et al, 1997).

Exposure

To expose the anterior surface of the prostate, it is necessary to displace the peritoneum superiorly. A malleable blade is used to retract the peritoneum superiorly and to gently displace the bladder posteriorly.

Figure 114-7. Incision in the endopelvic fascia and division of the puboprostatic ligaments. The incision in the endopelvic fascia is made at the juncture with the pelvic sidewall well away from the prostate and bladder. Anteriorly, near the puboprostatic ligaments, small arterial and venous branches from the internal pudendal vessels have been clipped and divided. The puboprostatic ligaments are divided superficially far enough down to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex. However, the pubourethral component of the complex is intact to preserve anterior fixation of the striated sphincter to the pubis. a., artery; v., vein. (© Brady Urological Institute.)

Incision in Endopelvic Fascia

The fibroadipose tissue covering the prostate is carefully dissected away to expose the pelvic fascia, puboprostatic ligaments, and superficial branch of the dorsal vein.

The endopelvic fascia is entered where it reflects over the pelvic sidewall, well away from its attachments to the bladder and prostate (Fig. 114-7). The point of incision is where the fascia is transparent, revealing the underlying levator ani musculature. Incision more medially can lead to entry into the lateral venous plexus of Santorini running alongside the prostate, resulting in persistent venous bleeding. Beneath this venous complex lie the prostatic arteries and the branches of the pelvic plexus that course toward the prostate, urethra, and corpora cavernosa.

The incision in the endopelvic fascia is then carefully extended in an anteromedial direction toward the puboprostatic ligaments. This allows the surgeon to palpate the lateral surface of the prostate. At this point, small arterial and venous branches from the pudendal vessels are encountered that perforate the pelvic musculature to supply the prostate. These vessels should be ligated with clips to avoid coagulation injury to the pudendal artery and nerve, which are located just deep to this muscle as they travel along the pubic ramus.

Division of the Puboprostatic Ligaments

The fibrofatty tissue covering the superficial branch of the dorsal vein and puboprostatic ligaments is gently teased away to prepare for division of the ligaments without injury to the superficial branch of the dorsal vein. After the superficial branch has been dissected away from the medial edge of the ligaments, it is coagulated and divided. After all fibrofatty tissue has been removed, a sponge stick is used to gently displace the prostate posteriorly and scissors are used to divide each ligament (see Fig. 114-7).

Figure 114-8. Preservation of bilateral large accessory pudendal arteries. The anterior prostatic fascia is elevated with a right-angled clamp to facilitate release of the accessory pudendal vessels. (© Brady Urological Institute.)

The dissection should continue down far enough to expose the juncture between the apex of the prostate and the anterior surface of the dorsal vein complex at the point where it will be divided. The pubourethral component of the complex should be spared to preserve the anterior fixation of the striated urethral sphincter to the pubis (Burnett and Mostwin, 1998).

Preservation of Accessory Pudendal Arteries

Arterial insufficiency is a factor contributing to erectile dysfunction in patients after nerve-sparing RRP. One source for this insufficiency may arise from accessory pudendal arteries that travel over the anterolateral surface of the prostate. These arteries have been found in 70% of cadaveric dissections and 7% of patients by selective internal pudendal angiography. Large visible accessory pudendal arteries are present in 4% of men (Rogers et al, 2004).

Because release of accessory arteries may be associated with significant blood loss necessitating prompt ligation and division of the dorsal vein complex, it is useful to have the contralateral dissection completed before accessory vessels are released. For this reason, when these vessels appear to be prominent and are present unilaterally, the endopelvic fascia and puboprostatic ligament on the contralateral side should be divided first. The surgical technique for preservation of the arteries begins with division of the endopelvic fascia lateral to the vessels and division of the puboprostatic ligament (the vessels are beneath the puboprostatic ligament) (Rogers et al, 2004). Next, a vessel loop is used to elevate the artery; then with sharp dissection and a right-angled clamp the accessory artery is released from its investing fascia (Fig. 114-8). As the dissection proceeds, venous tributaries are divided. At times, there may be substantial blood loss from the venous complex over the prostate; hemostasis, however, is usually easily obtained with a 4-0 running absorbable suture. The dissection must extend caudally beyond the site at which the dorsal vein complex will be divided.

Ligation of the Dorsal Vein Complex

The goal is to divide the complex with minimal blood loss while avoiding damage to the striated sphincter and inadvertent entry into the anterior apex of the prostate. With use of the sponge stick to push the prostate posteriorly, a 3-0 Monocryl suture is passed through the dorsal vein complex just distal to the apex of the prostate (Fig. 114-9). In placing this stitch, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient. Next, the needle is reversed in the needle holder and the same suture is placed through the perichondrium of the pubic symphysis (Fig. 114-10). Once this horizontal mattress

Figure 114-9. Steps in ligation and division of the dorsal vein complex. A 3-0 Monocryl suture is passed superficially through the dorsal vein complex just distal to the apex of the prostate. (© Brady Urological Institute.)

Figure 114-10. Next, the needle is reversed in the needle holder, and the same suture is passed through the perichondrium of the pubic symphysis. This maneuver is repeated to form a figure-of-eight horizontal mattress suture, which is then tied. (© Brady Urological Institute.)

suture is tied, three important goals are accomplished: (1) control of much of the venous bleeding without a “bunching” effect—this flat surface is much easier to divide; (2) recapitulation of the puboprostatic ligaments to provide additional anterior support of the striated sphincter; and (3) fixation of the dorsal vein complex anteriorly. This enables the surgeon to visualize the plane on the anterior apex of the prostate during division of the dorsal vein complex. The suture is not cut; it will be used once the dorsal vein is divided to oversee bleeders. Next a Babcock clamp is used to bunch the two edges of the endopelvic fascia. Then a figure-of-eight 2-0 Caprosyn suture is next placed through this bunched tissue on the anterior surface of the prostate near the bladder neck. This reduces bleeding from the proximal dorsal veins, which can be excessive in some patients who have incompetent venous valves (Fig. 114-11).

Apical Dissection

The apical dissection is the most complex and important step in the operation. The striated sphincter and the surrounding dorsal

Figure 114-11. A figure-of-eight 2-0 absorbable suture is placed on the anterior surface of the prostate to reduce bleeding from the proximal dorsal venous complex. v., vein. (© Brady Urological Institute.)

Figure 114-12. As Myers (1991) pointed out, there is marked variability in the shape of the apex of the prostate. In patients with a small prostate it can have a gentle slope, whereas in patients with an enlarged prostate, there can be an abrupt 90-degree angle. Knowledge of this variability is important to avoid excising excessive amounts of the striated sphincter. (© Brady Urological Institute.)

vein must be divided with care to avoid inadvertent incision into the apex of the prostate, the most common site for positive margins. Bleeding from the dorsal vein complex must be controlled without injury to the surrounding striated sphincter, the continence mechanism responsible for passive urinary control. During these maneuvers, the apical NVBs must not be injured by excessive traction, cautery, or inadvertent transection.

Division of the Dorsal Vein Complex. As Myers (1991) pointed out, there is marked variability in the shape of the apex of the prostate (Fig. 114-12). For this reason, we do not pass an instrument bluntly through the complex blindly. Rather, the dissection should be approached by direct division and visual assessment of the landmarks. With the application of gentle downward pressure on the anterior surface of the prostate with a sponge stick, Metzenbaum scissors or a No. 15 blade is used to divide the complex. This is usually started on the left edge of the complex where the junction with the apex of the prostate usually can be seen well (Fig. 114-13). Because the distal complex is fixed anteriorly, with downward pressure on the sponge stick, the exact plane between the juncture of the anterior surface of the prostate and the striated musculature can be visualized. Here loupes enable the surgeon to distinguish tissue textures and avoid positive margins. This is the most common site for positive surgical margins because it can be difficult to identify the anterior apical surface of the prostate. It also helps to rest the scissors on the anterior apex to find the correct plane.

There is one important caveat in performing this maneuver. As the dissection proceeds posteriorly, if the striated sphincter is

Figure 114-13. With a sponge stick depressing the prostate posteriorly, the dorsal vein complex is divided beginning at the left edge. (© Brady Urological Institute.)

Oversewing of striated urethral sphincter and dorsal vein

Figure 114-14. With the same 3-0 Monocryl suture that was used earlier to ligate the dorsal vein complex, the superficial edge of the distal striated urethral sphincter–dorsal vein complex is gently oversewn to perfect hemostasis. (© Brady Urological Institute.)

divided too close to the apex of the prostate, there is risk that the NVB may be damaged. As the NVB approaches the apex of the prostate, it is often fixed medially beneath the striated sphincter by an apical vessel (Walsh et al, 2000b). For this reason, the lateral edges of the sphincter along the urethra should be divided obliquely midway between the apex of the prostate and the pelvic floor. Absolute control of venous bleeding from the dorsal vein complex is mandatory so that the remainder of the procedure can be performed in a bloodless field. To achieve hemostasis, the 3-0 Monocryl suture on a $\frac{3}{8}$ -circle needle that was placed previously is used to oversee the superficial edges of the striated urethral sphincter–dorsal vein complex (Fig. 114-14). In placing this running suture, the surgeon should face the head of the table, holding the needle driver against the pubis perpendicular to the patient. If the needle driver is held loosely, the superficial edges of the complex can be easily approximated, forming a hood over the anterior urethra. Circumflex veins often are present at the posterior

Figure 114-15. The dorsal vein complex over the anterior surface of the prostate is oversewn in the shape of a V with a running 2-0 absorbable suture. (© Brady Urological Institute.)

edge of the complex at the 5- and 7-o'clock positions; hemoclips often are used to control these bleeders. At the completion of this maneuver, hemostasis should be excellent.

Finally, to control back-bleeding from the anterior surface of the prostate, the edges of the proximal dorsal vein complex on the anterior surface of the prostate are sewn together with the preplaced 2-0 absorbable suture (Fig. 114-15). By pulling these edges together, tension on the prostatic fascia is evenly distributed, which can facilitate high release of the nerve bundles if the surgeon chooses to perform this maneuver (see detailed description later).

Division of the Urethra and Placement of Urethral Sutures. The urethra should be divided first in performing a standard nerve release. If more aggressive nerve preservation is performed, the urethral incision should occur after nerve release (see later). By gently displacing the prostate posteriorly with a sponge stick, the prostatic-urethral junction should be well visualized. The lateral bands of the striated musculature should be released as described earlier at their midpoint to free up as much of the urethra as possible. A right-angled clamp is then passed around the smooth musculature of the urethra near the apex of the prostate to ensure that the urethra is transected as close to the apex as possible (Fig. 114-16). This maneuver defines several key anatomic landmarks at the apex. First it defines the posterior urethra from the posterior component of the striated sphincter. Second, if excellent hemostasis has been obtained, the association between the posterior striated sphincter and the nerve bundle should be able to be appreciated. With scissors, the anterior two thirds of the urethra is divided with care to avoid damage to the Foley catheter. This provides excellent exposure for placement of six sutures in the distal urethral segment at the 1-, 3-, 5-, 7-, 9- and 11-o'clock positions. With 3-0 Monocryl on a $\frac{5}{8}$ circle tapered needle, the needle should incorporate just the urethral mucosa and submucosa but not the smooth muscle (Fig. 114-17). As stated previously, the surgeon should face the head of the table to place these sutures and should hold the needle driver against the pubis perpendicular to the patient. The first suture is placed in the mucosa and submucosa of the urethra at the 1- and 11-o'clock positions. By use of a 16-Fr catheter, the mucosa is easily identified. The smooth muscle should not be incorporated in this stitch because stitches in the smooth muscle delay the recovery of urinary control. If the urethral tissue appears flimsy, this suture should then be placed through the dorsal vein complex to improve tensile strength.

Figure 114-16. A right-angled clamp is placed around the smooth muscle of the urethra close to the apex of the prostate. Note in the inset that the neurovascular bundles (NVBs) are protected from injury by the posterior component of the striated sphincter, which is still intact. Also see Figure 114-5. Post., posterior. (© Brady Urological Institute.)

Figure 114-17. The 3-0 Monocryl sutures are placed in the distal urethral mucosa and submucosa at the 12-, 2-, 10-, 7-, and 5-o'clock positions. The Foley catheter is then removed, the 6-o'clock suture is placed, and the posterior wall of the urethra is divided. Post., posterior. (© Brady Urological Institute.)

Once the mucosa and submucosa have been elevated by these stitches, the remaining sutures are more easily placed. We place all sutures from outside of the lumen to the inside; however, if sutures are more easily placed beginning on the luminal surface and then proceeding outside, a French eye needle can be used to place these sutures through the lumen of the bladder at the end of the case. The sutures are covered with towels to avoid inadvertent traction or displacement.

The posterior band of the urethra is now divided to expose the posterior portion of the striated urethral sphincter complex (see Fig. 114-17). The posterior wall of the striated sphincter complex is composed of skeletal muscle and fibrous tissue. Identification and precise division of this complex are important in (1) obtaining adequate margins of resection for apical lesions, (2) identifying the correct plane on the anterior wall of the rectum to ensure that all layers of Denonvilliers fascia are excised, (3) avoiding blunt trauma to the NVBs that are located immediately posteriorly, and (4) preserving urinary continence.

Figure 114-18. Division of the posterior component of the striated sphincter. A right-angled clamp is passed beneath the left edge of the striated sphincter midway between the apex of the prostate and urethra, at a site where the neurovascular bundles (NVBs) have fallen posteriorly. After the left edge of the complex is divided, a right-angled clamp is then passed along the right edge and the maneuver is repeated. post., posterior. (© Brady Urological Institute.)

To divide the posterior portion of the sphincter safely, a right-angled clamp is passed immediately beneath the left edge of this complex (Fig. 114-18). The clamp should pass midway between the apex of the prostate and the urethra. If it is passed too close to the apex of the prostate, it may damage the NVB. However, midway, the NVB is located more posteriorly and is beneath the right-angled clamp (Walsh et al, 2000b) (see Fig. 114-5).

The left border of the complex is then divided with scissors. Next, the right-angled clamp is placed beneath the right edge of the complex and the complex is divided. It is necessary to divide the complex from each side, because if division of the entire complex from one side is attempted, the contralateral NVB may be damaged. Finally, the central component of the complex is divided.

Identification and Preservation of the Nerve Bundle

Today, in most men who are candidates for surgery, it is safe to preserve both NVBs and rarely necessary to excise both of them (Walsh, 2001). With improved surgical techniques and the availability of phosphodiesterase type 5 inhibitors, most healthy potent men younger than 65 years should be potent after surgery. The neurovascular bundle is outside the prostate between layers of lateral pelvic fascia (the levator fascia and prostatic fascia). If nerve sparing is performed correctly, the prostatic fascia must remain on the prostate. This is called an *interfascial* dissection. Furthermore, when cancer extends through the capsule, it rarely penetrates more than 1 to 2 mm, and this much tissue is often present even when the neurovascular bundle is preserved (Hernandez et al, 2005). As Costello and colleagues (2004) have shown, the cavernous branches are positioned posterior to the capsular vessels and the nerves immediately adjacent to the prostatic capsule are nerves going into the prostate, not the cavernous nerves.

To avoid bleeding from the capsular arteries and veins, some surgeons dissect beneath the prostatic fascia. This is called an *intrafascial* dissection. Because this plane is directly on the prostatic parenchyma, the risk for positive surgical margins is high. For this reason, this approach should never be used. Many well-meaning surgeons believe that if they excise the NVB, they can avoid a positive surgical margin. Unfortunately, this is not the case because the NVB is not the most common site for positive margins. Rather, the most common site is the apex, followed by posterior and then posterolateral sites. In 22% the positive margins are multiple. In multiple studies, it has been demonstrated that the rate of positive margins in nerve-sparing and non-nerve-sparing procedures is the same (Ward et al, 2004). In Walsh's hands, the NVBs are preserved bilaterally in 87% of patients; one NVB is

excised in 13%. This has resulted in an overall rate of positive surgical margins of approximately 5% (Epstein, 2001). The NVBs are rarely if ever excised bilaterally. We have always thought that if there is capsular penetration bilaterally to the point at which it is necessary to excise both NVBs, the patient most likely has distant dissemination and is not curable. Between 1986 and 1999, only seven potent men had both NVBs excised. Four were not cured because they had positive lymph nodes, positive seminal vesicles, or positive surgical margins elsewhere. In the three other patients, it was not necessary to excise both NVBs because there was no capsular penetration on one side.

How is the decision made as to when and where to excise the NVB? Preoperatively, no definite decision is made. Consideration is given to the status of sexual function, but in impotent patients, we do not always excise the NVBs because there is evidence that the bundles provide both somatic and autonomic innervation to the continence mechanism and that patients who undergo excision of both NVBs have more incontinence than do patients in whom the NVBs are preserved (Nelson et al, 2003). Consideration is also given to other important factors such as the presence of a palpable apical lesion and a high probability of capsular penetration based on the Partin tables (Partin et al, 1997, 2001). However, no final decision is made until the time of surgery. When the endopelvic fascia is opened, if induration is palpable in the lateral pelvic fascia, the NVB on that side is widely excised. If there is no induration but the NVB appears to be fixed to the prostate at the time it is being released, it is also excised. However, the final decision about preservation or wide excision of the NVB does not need to be made until the prostate is removed. If there appears to be inadequate tissue over the posterolateral surface after the prostate has been removed, the NVB can then be widely excised.

Identification of the Neurovascular Bundle. This is where the tactile sensation provided by open surgery is so important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. Also, in gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be preserved. When the NVB is released, there should be no upward traction on the prostate. Rather, the prostate should be rolled from side to side. Also with the catheter out, the prostate is softer and it appears easier to identify the correct plane for release of the NVB.

Standard Preservation of the Neurovascular Bundles. Standard nerve release begins after incision of the urethra, placement of urethra sutures, and release of the posterior striated sphincter. Recall that the lateral pelvic fascia is composed of two layers: the levator fascia and the prostatic fascia. The NVB travels between these two layers (see Figs. 114-4B and 114-5). With a right-angled clamp, the superficial layers of levator pelvic fascia are released. The use of loupes is helpful during this maneuver to ensure the prostatic fascia has not been violated. The magnification also facilitates a more gentle dissection with less traction on the NVB. A Babcock clamp or sponge stick is used during release of the NVB to manipulate the prostate. The clamp facilitates gentle elevation of the prostate during the release and can result in less traction on the NVB because the prostate is released from the bundle rather than the bundle being released from the prostate. This dissection should begin at the bladder neck, where this fascia forms a thick band (Fig. 114-19). When this band is divided, the prostate immediately becomes more mobile. The superficial fascia should be released from the bladder neck to the apex. This maneuver releases the bundle laterally, thus making it easier to perform the next step, in which the bundle is released posteriorly at the apex.

Once the superficial fascia has been released, the location of the NVB can be identified by the presence of a subtle "groove" on the posterolateral edge of the prostate (Fig. 114-20). By tracing this groove to the apex of the prostate, one can determine where the NVB begins to travel caudally and laterally away from the prostatic apex toward the urethra. Once the medial border of the NVB has been identified at the apex, the dissection in the midline can be safely carried posteriorly toward the rectum.

Figure 114-19. The lateral surface of the prostate is exposed by displacing the prostate on its side with use of a Babcock clamp. A right-angled clamp is then inserted under the superficial layer of the levator fascia, beginning at the bladder neck and continuing all the way out to the apex. NVB, neurovascular bundle. (© Brady Urological Institute.)

Figure 114-21. At the apex, there are often prominent apical vessels. Because the prostate has been elevated on its side across the midline, note that the neurovascular bundle (NVB) appears to be kinked. If this artifact is not recognized, the NVB can be inadvertently transected. Once these vessels are clipped and divided, the NVB returns to its natural straight course. (© Brady Urological Institute.)

Figure 114-20. Once the levator fascia has been released, the neurovascular bundle (NVB) can be located by the presence of a subtle “groove” on the posterolateral edge of the prostate. This groove should be traced out to the apex of the prostate, and once the medial border has been identified, the dissection in the midline can be pursued, dividing residual layers of Denonvilliers fascia down to the rectum. (© Brady Urological Institute.)

Figure 114-22. The neurovascular bundle (NVB) has been released to just above the seminal vesicle. (© Brady Urological Institute.)

The plane between the rectum and prostate having been developed in the midline, it is then possible to release the NVB from the prostate, beginning at the apex and moving toward the base, elevating and displacing the prostate over on its side. Beginning on the rectal surface, the bundle is released from the prostate by spreading a right-angled clamp gently. At the apex, there are often prominent apical vessels (Fig. 114-21). Because the prostate has been elevated on its side across the midline, this distorts the direction of the NVB by kinking it (see Fig. 114-21). If this artifact is not recognized, the NVB can be inadvertently transected. These vessels should be clipped and divided. Once the dissection has been initiated at the apex, it should proceed to the midpoint of the prostate. Because the superficial layers of the levator fascia have already been released, this dissection often proceeds easily. Furthermore, in using this plane, the Denonvilliers fascia and prostatic fascia remain on the

prostate; only the residual fragments of the levator fascia are released from the prostate laterally. At this point in the procedure, the bundle should be released to the seminal vesicle (Fig. 114-22).

The vascular branches to the NVBs are best controlled by small hemoclips placed parallel to the bundle. Thermal energy of any form (unipolar, bipolar, or harmonic scissors) should never be used on the NVB or its branches (Ong et al, 2004). Usually it is not necessary to clip the prostatic side of these tiny vessels; fine scissors should be used to divide them. The number of arterial and venous branches is extremely variable. By starting at the apex, however, one can easily identify them prospectively. If the fixation of the bundle to the prostate cannot be explained by vascular branches, the NVB should be excised. The surgeon should be aware that the bundle may travel more anteriorly in some patients. In these patients, one can confuse the groove with the potential

Figure 114-23. Posterior dissection. The attachment of Denonvilliers fascia to the rectum is released, maintaining all layers of Denonvilliers fascia over the posterior surface of the prostate and seminal vesicles. Prominent branches from the neurovascular bundle (NVB) to the posterior surface of the prostate are identified at the posterolateral angle of the rectum. By dividing these posterior branches, the NVB is free to fall away from the prostate posteriorly. Post., posterior. (© Brady Urological Institute.)

space between the prostate and rectum. This is another good reason to release the bundle at the apex first. In addition, some patients have many veins on the lateral surface of the prostate that anastomose between the Santorini plexus anteriorly and the NVB posteriorly. The apical approach to the bundle facilitates management of this condition as well.

Furthermore, to make certain the Denonvilliers fascia is maintained on the prostate, the NVBs should be released by dissecting from the rectal surface anteriorly. Using the principles described previously, positive surgical margins in patients with organ-confined disease that are caused by inadvertently cutting into the prostate are rare. Also, because the NVB is more mobile, it is easier to interrogate the surgical field with tactile sensation and magnification to find the correct plane. For this reason, even in patients with extraprostatic extension in the region of the NVB, it is possible to partially excise the bundle, preserve potency, and obtain negative margins of excision (Hernandez et al, 2005).

To avoid traction on the NVB, this dissection should continue cephalad to the level of the seminal vesicles (Masterson et al, 2008). At this point, the surgeon should look for a prominent arterial branch traveling from the NVB over the seminal vesicles to supply the base of the prostate (Fig. 114-23). This posterior vessel should be ligated on each side and divided. In doing so, the NVBs are no longer tethered to the prostate and fall posteriorly.

High Anterior Release of the Neurovascular Bundles at the Apex. The purpose of this approach is to speed up the recovery of sexual function and continence by reducing traction on the branches of the nerves to the cavernous bodies and striated sphincter or to avoid inadvertent transection of the small branches that travel anteriorly (Costello et al, 2004; Takenaka et al, 2004, 2005; Horninger et al, 2005; Menon et al, 2005; Montorsi et al, 2005). However, because there is less soft tissue at the apex, the risk for positive surgical margins could be increased by this approach. We select candidates for this approach using parameters that identify patients with a low risk for extraprostatic extension in the region of the NVB (Tsuzuki et al, 2005). Tsuzuki and colleagues (2005) have defined preoperative parameters to identify patients with a higher likelihood of extraprostatic extension in the region of the NVB. If patients have two or more of the following criteria, the risk for extraprostatic extension in the region of the NVB on that side is greater than 10%: prostate-specific antigen (PSA) level above 10 ng/mL, Gleason score higher than 6,

average percentage of biopsy core on the side involved greater than 20%, percentage of cores with tumor on that side greater than 33%, or an abnormal finding on digital rectal examination.

The procedure begins after ligation of the dorsal venous complex and before incision of the urethra. Once total hemostasis is obtained, the levator fascia over the anterior apex of the prostate is incised and the incision is extended distally along the lateral edge of the apex of the prostate, preserving the underlying prostatic fascia (Fig. 114-24). The prostatic fascia is the glistening white fascia immediately below the veins that travel along the lateral surface of the prostate. To identify the correct plane and avoid inadvertent incision into the prostate, it is essential to have excellent visualization and magnification. In many patients, these venous tributaries must be divided and controlled. Cautery should not be used. Instead, hemostasis should be achieved by use of small hemoclips. As the dissection proceeds distally, the levator fascia should be released from the lateral shoulders of the prostate, with care taken not to enter the underlying prostatic fascia. Because the recovery of sexual function at 12 months after unilateral high release was the same as with bilateral high release, we now routinely perform it on only one side, the side with the most favorable pathologic status. Once the dissection has extended distally beyond the apex of the prostate, the NVB is exposed and released. Because the levator fascia has previously been released, prominent NVB usually can be visualized lateral to the urethra. At this point, as described by Masterson and colleagues (2008), the NVB is released from the lateral surface of the prostate to just above the seminal vesicles (Fig. 114-25). This approach avoids traction on the NVBs and makes the subsequent steps in preservation of the NVBs much easier (Fig. 114-26).

Next, the urethra is transected and urethral sutures placed. The posterior component of the striated sphincter is transected. If high release of the levator fascia was performed only unilaterally, a right-angled clamp is inserted under the levator fascia at the apex on the side contralateral to the high release. This facilitates identification of the same dissection plane beneath the levator fascia as the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside (see Fig. 114-26).

Wide Excision of the Neurovascular Bundles. Before excision of the NVB unilaterally, the contralateral NVB should be freed from the prostate, starting at the apex. This avoids traction injury, which can occur during wide excision of the contralateral bundle. The NVB to be excised is identified at the apex, and a right-angled clamp is passed from medial to lateral, immediately on the anterior surface of the rectum (Fig. 114-27). The bundle is divided without ligation in an effort to excise as much soft tissue as possible. Later, if bleeding is troublesome, the distal end can be clipped. The dissection is continued by dividing the fascia on the lateral surface of the rectum from the apex to the base so that the NVB and abundant fascial tissue are included in the specimen. This procedure is performed under direct vision, with the dissection terminating at the tip of the seminal vesicle, where the NVB is ligated and divided. In this way, the NVB and the lateral pelvic fascia are excised under direct vision in a more complete way than was previously possible (Fig. 114-28).

Posterior Dissection and Division of the Lateral Pedicles

Once the NVBs have been either preserved at the apex or widely excised and the prostate has been mobilized to the level of the seminal vesicles, the catheter is replaced and, with light upward traction on the catheter, the attachment between the rectum and Denonvilliers fascia is divided in the midline posteriorly (Fig. 114-29). Because the NVBs have been freed up, traction can be applied to the catheter to gain exposure to the base of the prostate and seminal vesicles. However, to improve exposure, the sponge stick should never be placed on the prostate itself because it may displace tissue, producing a false-positive margin. Instead, the sponge stick should be placed on the catheter. In developing this plane, all layers of Denonvilliers fascia should be left covering the seminal vesicles.

Figure 114-26. If high release of the levator fascia was performed only unilaterally, after the posterior component of the striated sphincter has been divided, a right-angled clamp is inserted under the levator fascia on the side contralateral to the high release at the apex. This facilitates identification of the same dissection plane beneath the levator fascia as the contralateral side without the need for approaching the plane by first dividing the levator fascia from the outside. (© Brady Urological Institute.)

At this point the lateral pedicle can be divided safely on the lateral surface of the seminal vesicles without injury to the NVB (see Fig. 114-29). The lateral pedicles are thick, and therefore they need to be divided in a sequential way: superficial, middle, deep (next to the seminal vesicles). If one tries to divide them all at once, this risks cutting into the overlying prostate.

Obvious arterial bleeders are simply controlled with hemoclips. With this approach, one can leave more soft tissue on the prostate and protect the NVBs from injury. The dissection proceeds superiorly onto the anterolateral surface of the junction between the bladder and the prostate. Finally, Denonvilliers fascia is divided over the tips of seminal vesicles to facilitate removal. At this point, many surgeons elect to divide the vasa deferentia and free up the seminal vesicles.

Figure 114-27. Wide excision of the neurovascular bundle (NVB). Once the contralateral NVB has been released and residual attachments of the rectum to the prostate at the apex are freed, a right-angled clamp is then passed directly on the anterior surface of the rectum from the midline laterally. If the right-angled clamp is passed lateral to medial, a rectal injury is more likely to occur. ant., anterior. (© Brady Urological Institute.)

Figure 114-28. Extent of the division of the neurovascular bundle (NVB) from the apex laterally to the tip of the seminal vesicle, where the NVB is ligated. This provides excellent soft tissue covering the primary lesion. (© Brady Urological Institute.)

Figure 114-29. Lateral view demonstrating the location of the neurovascular bundle (NVB) after ligation of the posterior branch to the prostate. The site for division of the lateral pedicle is indicated. The lateral pedicle is thick and should be divided in layers: 1, superficially; 2, in the middle; and then (3) deep next to the seminal vesicle. Trying to divide this thick pedicle all at once risks cutting into the overlying prostate. (© Brady Urological Institute.)

Division of the Bladder Neck and Excision of the Seminal Vesicles

The prostate has now been mobilized almost completely. The bladder neck is incised anteriorly at the prostatovesicular junction (Fig. 114-30). The incision is carried down to the mucosa, the mucosa is incised, the Foley balloon is deflated, and the two ends of the catheter are clamped together to provide traction. As the incision in the bladder neck is widened, branches running from the inferior vesical pedicle to the prostate are noted at 5- and 7-o'clock positions (Fig. 114-31). After these pedicles are divided, it should be possible to visualize the plane between the anterior surface of the seminal vesicles and the posterior wall of the bladder. By scissor dissection hugging the anterior surface of the seminal vesicles, the posterior bladder neck can be divided safely while observing the location of the ureteric orifices (Fig. 114-32).

After the posterior bladder wall is divided, the bladder neck is retracted with an Allis clamp, and the vasa deferentia are ligated with hemoclips and divided. The seminal vesicles are dissected free

Figure 114-33. Dissection of the vas deferens and seminal vesicles. The left vas deferens has been divided and ligated. The seminal vesicles are carefully dissected free from the pelvic plexus with direct visualization and ligation of small arterial branches. d., deferens. (© Brady Urological Institute.)

from surrounding structures (Fig. 114-33). Recall that the pelvic plexus is located on the lateral surface of the seminal vesicles. To avoid injury to the pelvic plexus, the surgeon should perform this dissection with great care, especially laterally, and under direct vision should identify the small arterial branches that travel to the seminal vesicles and stay close to the seminal vesicles when these small vessels are ligated with small clips. As the tips of the seminal vesicles are freed, small arterial branches at the tip of each seminal vesicle should be identified, ligated, and divided. Any residual attachments of Denonvilliers fascia are then divided, and the specimen is removed. The specimen is inspected carefully

to identify any areas where the margin of resection is uncertain. If there is any concern about the margin on the posterolateral surface of the prostate, the NVB on that side should be excised.

The operative site is inspected carefully for bleeding. **Small bleeding vessels near the NVB should not be cauterized, to avoid injury to the fine nerve fibers.** Bleeding from these small vessels should be controlled with small hemoclips. If not, the patient may develop a hematoma between the rectum and bladder. Inflammation surrounding the NVBs secondary to this hematoma may delay the return of sexual function (Walsh et al, 2000b). To avoid this adverse event, a small opening can be made in the peritoneum in the rectovesical cul-de-sac to facilitate decompression of a hematoma if it develops.

Bladder Neck Reconstruction and Anastomosis

The bladder neck is reconstructed with a running suture or interrupted 2-0 absorbable sutures to approximate full-thickness muscularis and mucosa, forming a tennis racquet closure (Fig. 114-34). At this point, it is useful to have previously injected indigo carmine to facilitate visualization of the ureteric orifices; ureteral catheters are not usually necessary. **By incorporating the mucosa in the closure, troublesome hematuria can be avoided.** The closure is initiated in the midline posteriorly and proceeds anteriorly until the bladder neck is narrowed to approximate the diameter of the urethra. Interrupted or running 4-0 absorbable sutures are used to advance the mucosa over the raw musculature of the bladder neck. In this way, a rosette of mucosa covers the bladder neck, facilitating a mucosa-to-mucosa urethrovesical anastomosis. The suture at the 6-o'clock position is left long to facilitate placement of the urethral sutures for the final anastomosis (see later).

At this point, the bladder neck can be anastomosed to the urethra, or buttressing sutures can be used to intussuscept the bladder neck (Walsh and Marschke, 2002). These sutures prevent the bladder neck from pulling open as the bladder fills. The standard surgical technique described in this chapter emphasizes ample margins to ensure excellent cancer control, especially at the apex. Some surgeons preserve the puboprostatic ligaments and dissect beneath them closer to the apical prostate. Although this may preserve more of the striated sphincter, there is concern that it may lead to inadequate apical margins. The technique described herein may excise more striated musculature, and consequently it takes longer for some men to be pad free. Walsh and colleagues found that with intussusception of the bladder neck, 80% of men are pad free at 3 months and 98% at 1 year (Parsons et al, 2004).

Figure 114-34. Tennis racquet closure of the bladder neck with a running 2-0 absorbable suture incorporating all layers of the bladder wall. The bladder mucosa is then advanced over the raw bladder edges with interrupted 4-0 absorbable suture material to ensure a mucosa-to-mucosa anastomosis. The posterior midline suture (at the 6-o'clock position) is left long. (© Brady Urological Institute.)

A 2-0 Maxon suture is placed into the edges of the posterior bladder wall, where the bladder was previously attached to the prostate, approximately 2 cm from the reconstructed bladder neck (Fig. 114-35). If any hemoclips are in this area, they should be removed because they may be folded into the bladder neck, causing a bladder neck contracture. The suture is tied in the midline. The next suture is placed more anteriorly. Before this suture is placed, it is wise to release tension on the anterior bladder wall by loosening the mal-leable blade. This will aid in identifying the loose perivesical tissue that should be incorporated into this stitch. A second figure-of-eight 2-0 Maxon suture is placed approximately 2 cm lateral to the bladder neck on each side (Fig. 114-36). At this point, the bladder neck should protrude beneath the anterior hood of tissue that was created by the anterior stitch, like a turtle that is poking its head outside its shell. When the bladder neck is filled with saline, it should be competent with little leakage. After this test is completed, the bladder should be emptied completely by placing a forceps through the bladder neck. The 6-o'clock suture should again be placed on traction to facilitate placement of the urethral sutures.

The operative site is inspected carefully for bleeding. A new silicone Foley catheter (16-Fr, 5-mL balloon) is placed through the urethra into the pelvis. The six 3-0 Monocryl sutures that were previously placed in the distal urethra are now placed through the

Figure 114-35. Intussusception of the bladder neck. bladder neck in their corresponding positions from inside to outside (Fig. 114-37). Use of traction on the 4-0 suture that was placed at the 6-o'clock position to exteriorize the mucosa facilitates placement of the sutures. As mentioned previously, a French eye needle is used for placement of the 12-, 2-, and 5-o'clock sutures. The catheter is irrigated free of clots, the balloon is tested, and the catheter is placed through the bladder neck and inflated with 15 mL of saline. The catheter is no longer placed on traction while the sutures are tied. Instead, a Babcock clamp, which is placed on the anterior bladder wall close to the reconstructed bladder neck, is used to hold the bladder in place while the sutures are tied (Fig. 114-38). This ensures excellent coaptation of the mucosa to mucosa and has markedly reduced the probability of bladder neck contractures.

The anterior suture is tied initially. There should be no tension. If there is, the bladder should be released from the peritoneum. The 2-, 5-, 10-, 7-, and 6-o'clock sutures are tied sequentially. After all sutures are tied, the catheter is manipulated to make certain it is not caught in one of the sutures. The catheter is irrigated with saline to eliminate clots. After the operative site is irrigated vigorously with saline, a small suction drain is placed through the fascia (away from the midline) and directed into the

operative site in the midline, between (not through) the rectus muscles. The incision is closed with a running No. 2 nylon suture and skin clips. The catheter is carefully taped to the thigh.

POSTOPERATIVE MANAGEMENT

The postoperative recovery of men who undergo open RRP is often uneventful. The complication rates after open radical RRP have greatly improved over the past decade and were recently reviewed (Dasgupta and Kirby, 2009). Summary of the findings showed a marked decrease in length of stay (now averaging 1.7 days), lower urine leak rates (0.17%), lower need for transfusion (0.13%), lower postoperative ileus rate (0.6%), and a lower re-exploration rate for hemorrhage (0.08%).

Traditionally, men ambulate the evening of the procedure and are discharged on postoperative day 1 or 2. Pain control is achieved by intravenous patient-controlled analgesia with Dilaudid, fentanyl, or morphine on the night of surgery. In an effort to decrease the need for narcotics after surgery, men with normal renal function (preoperative creatinine < 1.2 mg/dL), no excess blood loss during the procedure (estimated blood loss < 1500 mL), and no history of uncontrolled diabetes or postoperative hematuria have received a dose of intravenous ketorolac tromethamine, a nonsteroidal anti-inflammatory drug (NSAID) either before transfer to the recovery room or the morning after surgery. Recently, intravenous acetaminophen also has been administered to men for postoperative pain control with similar results but at present is quite costly. This combination of analgesic agents reduces postoperative ileus; however, when NSAIDs are used we have seen postoperative hematuria persist, often requiring repeated catheter irrigation. Patients are offered a clear liquid diet on the evening of surgery and a regular low-fat diet the next day. A single closed-suction drain is left in place until discharge or it produces less than 50 mL/day off of suction.

The urinary catheter is left in place for 7 to 10 days postoperatively, represents a source of significant bother (Lepor et al, 2001), and limits the return to activities and work (Sultan et al, 2006). Therefore the urinary catheter should be removed as soon as possible without compromising outcomes (e.g., urinary retention and bladder neck contracture). Most would agree that removing the urinary catheter in the presence of significant urine extravasation would be unwise. Although 80% of vesicourethral anastomoses exhibit no evidence of cystographic extravasation by the fourth postoperative day, removal of the urinary catheter at this time is not recommended because of the high rate of acute urinary retention (Patel and Lepor, 2003). Approximately 10% of men will exhibit moderate extravasation on postoperative cystograms performed 1 week after surgery. Routinely performing cystography at 1 week allows "early" removal of the urinary catheter while also identifying the small subset of men who might benefit from longer bladder drainage but requires patients to return to the hospital/clinic, exposes them to radiation, and incurs additional expense to the process. Alternatively, our experience has shown that the urinary catheter may be removed safely by the patients in their own home after 10 days. Bladder spasms will generally spontaneously subside, and reassurance is often sufficient. In cases of severe bladder spasms, an oral anticholinergic agent (oral oxybutynin [Ditropan] 5 mg) or diazepam (oral Valium, 5 to 10 mg) may be administered.

COMPLICATIONS

RRP is well tolerated, with minimal morbidity and low mortality (0.2%). Complications can be divided into those occurring intraoperatively and those occurring postoperatively.

Intraoperative Complications

The most common intraoperative problem is hemorrhage, usually arising from venous structures. Venous injury often can be

Figure 114-37. The bladder neck is exposed by placing traction on the 4-0 absorbable suture at the 6-o'clock position. The final anastomosis is performed by placing 3-0 Monocryl sutures at the 12-, 2-, 5-, 7-, and 10-o'clock positions. (© Brady Urological Institute.)

Figure 114-38. A Babcock clamp is used to displace the reconstructed bladder neck into the pelvis and is held in place until all sutures are tied. This maneuver ensures that there is excellent coaptation of the reconstructed bladder neck to the urethra while the sutures are being tied. (© Brady Urological Institute.)

controlled temporarily with packing, exposure, and suture or surgical clip ligation. If this is not successful, fine (No. 5-0) cardiovascular sutures may be required. Hemorrhage also can occur during incision in the endopelvic fascia, during division of the puboprostatic ligaments, or during exposure of the apex of the prostate with transection of the dorsal vein complex. If one understands fully the anatomy of the dorsal vein complex, this bleeding is usually satisfactorily controlled once the dorsal vein has been divided and carefully suture ligated. If there is troublesome bleeding from the dorsal vein complex at any point, the surgeon should completely divide the dorsal vein complex over the urethra and oversew the end. This is the single best means to control bleeding from the dorsal vein complex. While obtaining exposure for the prostatectomy, gentle traction must be put on the prostate. If the dorsal vein is not completely divided and ligated, this traction opens the partially transected veins and usually worsens the bleeding. With careful technique and a thorough knowledge of anatomy, the average blood loss during radical prostatectomy is 300 to 1000 mL routinely and rarely (<1%) requires intraoperative homologous blood transfusion. Because of these low transfusion rates, we no longer require the patients to donate/bank autologous blood before surgery. Every case does, however, get a type and screen sample obtained before initiation of surgery.

Less common intraoperative complications include obturator nerve injury during pelvic lymph node dissection, rectal injury, and ureteral injury. If the obturator nerve is inadvertently severed, an attempt should be made at reanastomosis with fine nonabsorbable sutures. Rectal injury is an infrequent (<0.3%) but serious complication. Rectal injury occurs during apical dissection in attempting to develop the plane between the rectum and Denonvilliers fascia. When a rectal injury occurs, the prostatectomy should be completed, the bladder neck should be reconstructed, and hemostasis should be excellent. It is critical to attempt to interpose omentum between the rectal closure and the vesicourethral anastomosis to reduce the possibility of a rectourethral fistula. This maneuver can be accomplished simply by making a small opening in the peritoneum; finding the omentum and fashioning a slender, well-vascularized pedicle that will be long enough to reach the pelvic floor; dividing the peritoneum in the rectovesical cul-de-sac; and feeding the end of an omental pedicle through this opening. The anal sphincter is digitally dilated widely by an assistant, and the rectal injury is clearly delineated. With excellent visualization, the edges of the rectal wound are freshened and closed in two layers. The omental pedicle is immobilized over the repair, with absorbable sutures, and the vesicourethral anastomosis is performed. The wound should be copiously irrigated with antibiotic solution, and the patient should be maintained for several days on broad-spectrum antibiotics for both aerobic and anaerobic bacteria. When this technique was used, all recovered without development of a wound infection, pelvic abscess, or rectourethral fistula (Borland and Walsh, 1992). However, if the patient has received prior radiotherapy (salvage prostatectomy), it is prudent to perform a diverting colostomy. Ureteral injury is also very rare and usually occurs secondary to inadvertent dissection within the layers of the trigone while attempting to identify the proper cleavage plane between the bladder and seminal vesicles. If this injury occurs, ureteral reimplantation should be undertaken.

Postoperative Complications

Life-threatening delayed hemorrhage is a rare complication of RRP. Significant bleeding after radical prostatectomy is defined as postoperative hemorrhage requiring the acute transfusion of blood to support blood pressure (Hedican and Walsh, 1994). Rarely a patient will require exploration for delayed bleeding, and most cases are managed expectantly. The mean blood product requirements for patients who were explored were comparable with those for patients managed conservatively, although total hospitalization was shorter in patients who underwent a secondary operation. In patients managed nonoperatively, the pelvic hematoma may drain through the urethrovesical anastomosis, resulting in symptomatic bladder

neck contractures and long-term problems with urinary control. In our experience (Hedican and Walsh, 1994) only 25% of men explored for delayed bleeding experienced prolonged mild incontinence. These results suggest that patients requiring acute transfusions for severe hypotension after radical prostatectomy should be explored early to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.

Thromboembolic Events

Deep venous thrombosis (DVT) with pulmonary embolism is a major cause of mortality after radical prostatectomy. This recent review of over 45,000 surgical prostate procedures completed in Sweden demonstrated that the highest rates were seen when pelvic lymph node dissection was performed as part of the procedure and that the highest likelihood occurred between 14 and 28 days after the procedure, highlighting the need for continued attention to risk as long as 4 weeks after the procedure. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, use of intermittent compression devices, and early ambulation. With an 8-cm incision, Walsh did not have a thromboembolic event in over 700 cases, in contrast to a rate of 1.4% in his prior 700 cases (Walsh, personal communication). Although the mechanism behind this dramatic reduction is unknown, Walsh thinks that the shorter incision reduces exposure, dehydration, and traction on the external iliac veins during the procedure. Mini-dose heparin or low-dose, low-molecular-weight heparin is used at some centers (but not at ours).

Most importantly, all patients should be repeatedly informed of the signs and symptoms of DVT and pulmonary embolism before discharge and should be instructed verbally and in writing to call immediately if they have any of the following symptoms: swelling or pain in the leg, especially in the calf; sudden chest pain that is worse on taking a deep breath; hemoptysis; shortness of breath; or the sudden onset of weakness or fainting. We have found that the informed patient is the best way to reduce the morbidity and mortality from thromboembolic events. When patients develop DVT or pulmonary embolism events, twice-daily subcutaneous administration of low-molecular-weight heparin without monitoring of clotting factors appears to be at least as effective and safe as an adjusted-dose, intravenous administration of unfractionated heparin (Buller et al, 2003).

Bladder Neck Contracture

Bladder neck contractures historically occur in 0.5% to 10% of patients after radical prostatectomy, and the rate has diminished dramatically over the last decade. They arise from inadequate coaptation of the mucosal surfaces. This may be due to inadequate approximation at the time of surgery, urinary extravasation, or distraction of the bladder neck from a hematoma. The diagnosis should be considered in any patient who complains of a poor urinary stream or in patients who have prolonged unexplained incontinence. If treatment with simple cystoscopic dilation fails, direct cold-knife incision of the bladder neck at 3-, 6-, and 9-o'clock followed by intermittent self-catheterization for a limited time usually corrects the problem. In patients with recalcitrant bladder neck contractures, the injection of triamcinolone acetate (200 mg in 5 mL) at the bladder neck after cold-knife incision may be useful.

Urinary Incontinence

After radical prostatectomy, incontinence is usually secondary to intrinsic sphincter deficiency. Kim and associates (2013) demonstrated in a Surveillance, Epidemiology, and End Results (SEER) Program population that only 6% of over 16,000 men (over age 65) had undergone an "incontinence procedure" within the first 2 years after prostatectomy. In some men, the striated sphincter may

be poorly developed; in older men, it is thinner and contains more collagen (Burnett and Mostwin, 1998; Strasser et al, 1999). However, the predominant cause of this deficiency is injury during ligation and division of the dorsal vein complex. The smooth musculature of the urethra, which also contributes to continence, can be damaged by placement of large, deep sutures for the anastomosis or denervated by injury to the NVBs. Furthermore, the bladder neck must be supple, with a diameter that is not excessively large, because urinary continence can be hampered by the development of a bladder neck contracture or a wide bladder neck (Horie et al, 1999; Groutz et al, 2000). To avoid these complications, as outlined previously, it is important to preserve the striated sphincter during the apical dissection, to avoid tension on the final anastomosis, to reconstruct the bladder neck so that the opening is small and supple, and to accomplish a precise mucosa-to-mucosa anastomosis. Buttressing sutures to intussuscept the bladder neck to prevent it from pulling open as the bladder fills also have been reported (Walsh and Marschke, 2002). Finally, many men have detrusor hypertrophy and decreased bladder compliance from preexisting bladder outlet obstruction. It takes these patients longer to achieve full urinary control. For this reason, it is important to avoid excessive traction on the bladder intraoperatively, which may aggravate this condition.

It is beyond the scope of this chapter to review all of the literature on urinary incontinence. In a population-based longitudinal cohort follow-up study up to 24 months, Stanford and colleagues (2000) reported that after radical prostatectomy, 8.4% of men had either frequent urinary leakage or no control. In contrast, in the patient-reported outcome study by Walsh and associates (2000a) in which patients returned a validated questionnaire to an independent third party, 93% of the patients were wearing no pads at 1 year and 98% stated that they had no significant urinary problem. In a more recent study performed after introduction of the bladder neck intussusception, 98% of the patients were pad free at 1 year and no patient reported having a significant problem with urinary control (Parsons et al, 2004).

During their recovery, patients need constant encouragement and advice at regular intervals. The details of this program are reported elsewhere (Walsh and Worthington, 1995, 2001). Until urinary control has returned completely, patients are advised to reduce their fluid intake, avoid caffeinated beverages and alcohol, and stop α -adrenergic antagonists if they take them for the treatment of hypertension. Treatment with imipramine or α agonists in men who are not hypertensive can be helpful.

Erectile Dysfunction

Three factors are important in the recovery of erectile function after radical prostatectomy: age of the patient (younger than 65 years), status of potency preoperatively, and ability to intraoperatively preserve both NVBs. Walsh and colleagues (2000a) evaluated incontinence by a validated questionnaire sent to an independent third party for review. At 18 months, 86% of the patients were able to have unassisted intercourse with or without sildenafil citrate. Although a third of patients were taking sildenafil citrate, only 4% of men reported that they could not have intercourse without it. The recovery of sexual function occurred gradually: 38% were potent at 3 months, 54% at 6 months, 73% at 12 months, and 86% at 18 months. Recovery of sexual function also correlated with the age of the patient at the time of surgery: 100% in men 30 to 39 years, 88% in men 40 to 49 years, 90% of men 50 to 59 years, and 75% in men 60 to 67 years. These data were updated with a similar questionnaire (Parsons et al, 2004). At 3 months, 42% of the patients were potent; at 6 months, 49%; and at 1 year, 73%. In both series, most patients had both NVBs preserved. In patients in whom only one NVB is preserved, 65% of patients are potent. In patients with an accessory pudendal artery, preservation was associated with a twofold increase in the likelihood of recovery of erections (Rogers et al, 2004).

 High anterior release of the NVB as demonstrated in the video on the Expert Consult website is associated with significantly earlier recovery and return to baseline sexual function. In potent

men undergoing high anterior release, 93% were potent 12 months after surgery and 70% reported a return to their baseline erectile function. In men who preoperatively reported a frequency of intercourse more than once per week, 78% reported a return to their baseline sexual function at 12 months (Nielsen et al, 2008). Interestingly, this recovery and return to baseline function was noted in men who underwent either a unilateral or bilateral high release. This suggests that the improved sexual recovery associated with this technique is not likely due to preservation of anterior branches of the cavernous nerves but rather to improved accuracy in the preservation of the nerves with less traction. Other experienced surgeons also have noted improved recovery of sexual function using similar early nerve release techniques providing further merit to this technical modification (Masterson et al, 2008).

In patients who are medically cleared, phosphodiesterase type 5 (PDE5) inhibitors augment sexual recovery after radical prostatectomy. Until recently, however, the best dosing schedule (nightly or on demand) for these medications was unclear. In a small study, Padma-Nathan and associates (2008) reported improved recovery of sexual function in patients given nightly sildenafil versus patients given placebo. However, men in the placebo arm never received any therapy. In 2008, Montorsi and colleagues reported on a multi-institution randomized, double-blind study examining recovery of erectile function using either vardenafil "on demand," nightly, or placebo for 9 months. At the end of the blinded treatment period, vardenafil on demand was of greater benefit than nightly treatment. In a similarly devised trial, Pavlovich and colleagues (2009) noted no difference in recovery of sexual function in patients using either on-demand or nightly sildenafil, with a trend toward improved recovery in the on-demand arm. Thus on-demand dosing of PDE5 inhibitors appears to be the most effective method to aid in recovery of sexual function.

SURGICAL MODIFICATIONS TO CLASSIC ANATOMIC RADICAL PROSTATECTOMY

Since the initial report of the anatomic radical prostatectomy, refinements in the surgical technique have been made. Some modifications have minimized the short-term and long-term morbidity of the procedure or the oncologic outcome and have been incorporated into the classic operation (Walsh et al, 2000b; Walsh and Marschke, 2002; Rogers et al, 2004); others have demonstrated no or minimal measurable benefit or negative benefit and have been abandoned (Steiner et al, 1993; Parsons et al, 2004). Several modifications to the classic anatomic radical prostatectomy have been suggested to improve early return of urinary continence, erectile function, or both. These surgical modifications have focused on the function of the bladder neck in urinary control, dissection around the seminal vesicles, and placement of interposition nerve grafts when resection of the NVBs is required. Compelling anatomic and physiologic mechanisms have been proposed to explain how these modifications improve continence and potency. The evidence supporting these modifications is less compelling and often inconsistent. Retrospective studies comparing the impact of these technical modifications on quality-of-life outcomes fails to control for selection bias, varying methods for assessing outcomes, and varying skills of the surgeons performing the modified versus standard surgical techniques. These retrospective studies are appropriate for identifying a signal of clinical benefit. Ultimately, long-term randomized multicenter studies using validated quality-of-life questionnaires must be performed before these modifications become standard of practice, especially because these modifications have the potential to cause unexpected complications and may have a negative impact on oncologic control. One surgical modification that merits discussion for historical interest is the bladder tube to improve urinary continence outcomes. The initial reports suggested clinical benefit (Steiner et al, 1993; Seaman and Benson, 1996). Today, this surgical modification is no longer recommended, presumably because of high rates of anastomotic strictures, which most likely compromised urinary continence.

Bladder Neck (Sparing) Preservation

Investigators have proposed that preservation of as much of the bladder neck as possible at the time of removal of the prostate can hasten return of urinary control after RRP (Klein, 1992; Licht et al, 1994; Braslis et al, 1995; Lowe, 1996; Shelfo et al, 1998; Poon et al, 2000; Soloway and Neulander, 2000; Srougi et al, 2001; Deliveliotis et al, 2002). Klein (1992) was the first to suggest that modification of the bladder neck resection and reconstruction at the time of RRP might influence urinary control. The group at the University of Miami has reported on a large nonrandomized series of men who underwent RRP with bladder neck preservation (Braslis et al, 1995; Soloway and Neulander, 2000). In 2000 they reported only a 1% bladder neck contracture rate and 1% positive margins at the bladder neck site only and suggested that “extensive” resection at the bladder neck did not add to the curative nature of the procedure yet did not elaborate in detail on the return of urinary control.

In 1996, Lowe compared bladder neck preservation with bladder neck resection (classic method) in a nonrandomized group of nearly 200 men divided between bladder neck preservation and excision. No difference was seen in positive margins, and bladder neck preservation hastened the return of urinary control but did not improve overall continence in the long term (Lowe, 1996). Poon and colleagues (2000) and the group from Loma Linda also reported on a comparative study of 220 men divided into three groups: bladder neck preservation, classic tennis racquet closure, and anterior bladder tube reconstruction. Bladder neck contracture occurred in 10% overall and in 5%, 11%, and 18% by group, respectively. Urinary continence, ascertained by third-party telephone interview, demonstrated 12-month rates of 93%, 96%, and 97% by group, respectively (no difference). These authors concluded that there was no major difference between groups with respect to return of urinary control. Similarly, Deliveliotis and colleagues (2002) showed no difference in continence rates in the long term (1 year) but significant difference ($P < .05$) in the short term (3 to 6 months) when preservation of the bladder neck was exercised.

In several series, higher positive surgical margins were seen with bladder neck preservation. Srougi and colleagues (2001) from São Paulo, Brazil, reported on a planned enrollment of 120 men in a truly randomized trial between bladder neck preservation and classic reconstruction. Enrollment was stopped because the rate of positive surgical margins in the preservation arm was 10-fold higher (10% vs. 0%) compared with the classic reconstruction arm. Within the group of 70 who finished the trial, the authors measured continence rates and found no difference concluding that the external sphincter appears to play a more important role than the bladder neck in continence after radical prostatectomy. Marcovich and colleagues (2000) also demonstrated that bladder neck-sparing surgery resulted in significantly higher rates of positive surgical margins at the bladder neck compared with standard RRP (47% vs. 20%).

The feasibility of the Heidelberg technique for complete bladder neck preservation, which involves preservation of bladder neck circular fibers and urethra-urethral anastomosis, has been reported (Nyarangi-Dix et al, 2013). Nyarangi-Dix and coworkers (2013) randomized 208 candidates for open RRP or robotic-assisted laparoscopic radical prostatectomy to standard versus Heidelberg complete bladder neck preservation technique. Continence was assessed at 0, 3, 6, and 12 months by the 24-hour pad test, social continence by the number of pads per day, and quality-of-life outcomes by the validated Incontinence Quality of Life Questionnaire. Oncologic control was assessed by surgical margin status. At 0, 3, 6, and 12 months the mean loss of urine in the standard versus complete bladder neck preservation groups were 713 versus 237 g, 50 versus 16 g, 44 versus 6 g, and 25 versus 3 g, respectively. The percentage of men who were socially continent (use of none or one pad in 24 hours) at 3, 6, and 12 months in the standard versus complete bladder neck preservation groups were 55% versus 84%, 75% versus 90%, and 81% versus 90%, respectively. At all times, mean urine volume and percent of men socially continent was significantly greater in the complete bladder neck resection group. The positive

surgical margin rates between the standard (13%) versus complete bladder neck preservation (15%) groups were not significantly different, and the overall rate is similar to other contemporary series from high-volume centers (Razi et al, 2009). Although most positive surgical margins do not translate into disease recurrence, those occurring at the bladder neck are most worrisome (Razi et al, 2009). Only 2% of cases had positive surgical margins at the bladder neck. No mention was made if these bladder neck margins occurred in the standard or bladder neck preservation groups. It is unclear whether enrollment into the study was influenced by prostate cancer risk group. Overall, the 36% rate of pT3 disease is comparable to that in other series reported from high-volume centers (Poon et al, 2000). Nine percent of men randomized to complete bladder neck preservation were excluded from treatment analysis. The significant advantage of continence in the complete bladder neck preservation group was not observed at 12 months using an intent-to-treat analysis. The one potential complication of bladder neck preservation is bladder neck contracture. The authors make no mention of the rate of bladder neck contracture.

All would agree that the number one goal of anatomic radical prostatectomy is cancer control. These studies seem to agree that there is little difference in the positive margin rates (bladder neck only) with this modification. The randomized controlled trials suggest that there is a clinically significant difference in urinary continence up to 6 months that diminishes and is questionably clinically significant at 1 year. Finally, the high rate of bladder neck contracture and positive margins in some, but not all, studies makes this modification less than desirable. Long-term oncologic outcomes from the Heidelberg experience will provide the definitive evidence whether cancer control is compromised. Although the risks need to be weighed against the benefits, this modification warrants consideration. We do not perform bladder neck-sparing surgery.

Seminal Vesicle Sparing

The dramatic stage shift witnessed during the past two decades (Han et al, 2004) primarily brought about through early detection with PSA, has dramatically decreased the numbers of men presenting with regionally advanced disease (T3b) within the seminal vesicles (Poon et al, 2000; Han et al, 2001). Seminal vesicle involvement has been widely accepted as a poor prognostic feature; however, contemporary studies have demonstrated that few men (<5%) presenting with localized prostate cancer (near 0% in cT1c) have disease that has already spread to the seminal vesicle (Poon et al, 2000). Are we removing this tissue unnecessarily? Some investigators suggested that the close approximation of the seminal vesicles to the NVB, pelvic plexus, and bladder base and neck blood supply may allow the dissection in this area to play a major role in post-operative urinary and erectile function and have developed algorithms to predict seminal vesicle involvement before surgery (reviewed by Zlotta et al, 2004).

A modification to the classic anatomic radical prostatectomy has been proposed—seminal vesicle sparing. Korman and colleagues (1996) were the first to investigate the importance of complete resection of the seminal vesicle during RRP. They investigated the incidence of histologic evidence of cancer within the distal 1 cm of seminal vesicle tissue in 71 consecutive RRP specimens. Of 71 specimens, 12 had seminal vesicle invasion and 0 (0%) had disease in the distal 1 cm of the seminal vesicles bilaterally, which led the investigators (who advocated complete resection of the seminal vesicles at that time) to suggest that it is not necessary to remove the seminal vesicle in its entirety when the dissection is difficult. This might eliminate the potentially damaging dissection near other important anatomic structures.

In a follow-up study, Theodorescu and colleagues (1998) looked at the importance of complete seminal vesicle excision by comparing RRP with radical perineal prostatectomy (RPP). In two similar groups (stage, race, age, PSA level, and grade), 64% underwent RRP and 36% underwent RPP (seminal vesicles are not routinely removed). In the follow-up period, 45% of the men

in the perineal prostatectomy group demonstrated biochemical (PSA) elevation (>0.2 ng/mL) compared with only 18% in the retropubic prostatectomy group. When they broke down the perineal prostatectomy group on the basis of no seminal vesicle excision or seminal vesicle excision, the PSA recurrence rate was 69% versus 20%, respectively. The authors concluded that complete excision of the seminal vesicle during radical prostatectomy is essential for cancer control.

John and Hauri (2000) investigated the influence of seminal vesicle preservation during RRP on urinary continence. They observed 54 men, of whom 34 underwent RRP with seminal vesicle removal and 20 with seminal vesicle preservation. A modified pad test at 6 weeks and 6 months postoperatively demonstrated continence rates of 60% at 6 weeks and 95% at 6 months for the seminal vesicle preservation group compared with 18% at 6 weeks and 82% at 6 months for the seminal vesicle resected group. They concluded that seminal vesicle preservation may preclude damage to the pelvic nerves and maintain urinary continence during RRP.

Albers and associates (2007) reported the results of a trial of 317 men with PSA of 10 ng/mL or less, biopsy Gleason score 7 or less, and a total prostate volume of 50 mL or less randomized to standard RRP versus seminal vesicle-sparing RRP. Potency, lower urinary tract symptoms (LUTS), and continence were evaluated at baseline and multiple intervals postoperatively between 4 weeks and 1 year using the International Index of Erectile Function (IIEF), International Prostate Symptom Score (IPSS), and assessment of pad usage, respectively. Continence was defined as 0 to 1 pads over a 24-hour interval and potency by an IIEF score greater than 15. The primary limitations of the study design were that outcome assessments were conducted by the urologist and the longest follow-up was only 1 year. The continence rates at 4 weeks (62% vs. 45%) and 12 months (96% vs. 86%) were significantly higher in the seminal vesicle-sparing group. Potency rates and the oncologic assessment were similar at 1 year. The small number of evaluable men at 1 year limits the reliability of these observations.

Mogorovich and associates (2013) examined the incidence of painful orgasm after radical prostatectomy. A questionnaire capturing several sexual function domains, including painful orgasm, was mailed to 1411 men who had undergone radical prostatectomy at a single institution between 2002 and 2006. Overall 11% of men completing the retrospective survey reported experiencing pain with orgasm and men undergoing bilateral seminal vesicle-sparing radical prostatectomy were 2.33 times more likely to have painful orgasms than men undergoing complete excision of the seminal vesicles. The incidence of painful orgasm for those men undergoing bilateral excision of the seminal vesicles was similar to that of age-matched men without prostate cancer. Therefore painful orgasm is likely a consequence of seminal vesicle preservation and should be considered in assessing the risk-benefit ratio of this procedure.

Zlotta and coworkers (2004) proposed performing excision of the seminal vesicles in men with PSA of 10 ng/mL or greater, biopsy Gleason score of 6 or greater, or more than 50% of biopsy cores positive for prostate cancer. Secin and associates (2009) conducted a decision analysis applying these criteria to 1406 men who underwent radical prostatectomy at their institution and, based on a calculated intermediate risk-benefit ratio of seminal vesicle excision, recommended rejection of the recommendations of Zlotta and coworkers.

The clinical evidence suggests that most men with low-risk disease can safely undergo seminal vesicle preservation. Because the nononcologic risks and benefits are uncertain, assuming any compromise of oncologic control remains a concern. Clearly, a double-blind (patient and third-party reviewer) randomized trial of this method must be performed to fully understand the conflicting results.

We do not perform seminal vesicle-sparing surgery. However, in low- and intermediate-risk disease cases in which the seminal vesicles are very large or encased in scar, we see little harm in not excising the distal-most aspect of the seminal vesicle.

Interposition Nerve Grafting

Although wide resection of both NVBs is rarely indicated when curative intent is the desired effect for anatomic radical prostatectomy (Walsh and Worthington, 2001), investigators have suggested interposition sural nerve grafts after unilateral and bilateral NVB resection during RRP (Kim et al, 1999, 2001a, 2001b, 2001c; Scardino and Kim, 2001; Walsh, 2001; Singh et al, 2004). Early studies in the rat provided experimental evidence documenting the beneficial effect of interposition nerve grafting after unilateral or bilateral cavernous nerve damage or resection (Burgers et al, 1991; Quinlan et al, 1991b; Ball et al, 1992a, 1992b). However, in humans, as opposed to the rat, the cavernous nerves are composed of many fibers that are separated by as much as 3 cm (Costello et al, 2004; Takenaka et al, 2004). This raises the legitimate question of whether it is possible to perform a classic end-to-end nerve graft. The precise pathophysiologic mechanism of cavernous nerve regeneration has yet to be fully understood; however, basic science studies and human clinical testing have suggested that return of parasympathetic function can be demonstrated after interposition grafting of the brachial plexus, facial nerves, and peripheral nerves.

It is universally accepted that preservation of erectile function after radical prostatectomy is quantitatively related to preservation of the autonomic innervation and that, with resection of both NVBs, recovery of erectile function satisfactory for spontaneous erection and intercourse is limited (Quinlan et al, 1991a). Kim and colleagues (1999) first suggested interposition sural nerve grafting at the time of anatomic radical prostatectomy to replace resected cavernous nerves. This group later reported on 28 men with bilateral non-nerve-sparing radical prostatectomy who underwent bilateral sural nerve grafts with 12-month follow-up that 26% had unassisted erections sufficient for intercourse, 26% had partial erections, and 43% had erections sufficient for intercourse with the aid of sildenafil citrate (Kim et al, 2001a). Sexual function returned 5 months after grafting at the earliest time. Another group (Singh et al, 2004) investigated the return of urinary control with respect to sural nerve grafting. They reported a series of 111 men with purposeful unilateral nerve excision, 53 of whom underwent unilateral sural nerve graft after the prostatectomy. At 12 months, 95% of the grafted group reported "complete" urinary control (leakage of only a few drops) compared with only 53% of the nongrafted group ($P < .012$). The authors suggested that the cavernous nerves may play a role in return of continence. These findings have yet to be validated and should be viewed cautiously until a randomized study can be conducted.

Most urologists performing RRP and NVB excision require the participation of a plastic surgeon to perform the harvest and implantation of the nerve graft material. Kim and Seo (2001) suggest that with experience, the urologic oncologist performing the RRP should feel comfortable with harvest of the nerve and placement of the graft with limited impact on surgical time and blood loss. Technically, the sural nerve (width of 1.5 to 3 mm, ovoid) graft is harvested with iris scissors through a 3-cm incision that is placed 1 cm inferior to the lateral malleolus. The saphenous vein will be encountered. Dissection should be carried out with loupe magnification. The nerve is divided at the distal end and the foot-side end fulgurated. A tendon stripper (6 mm in diameter) is used to strip the nerve proximally for approximately 20 cm toward the back of the calf, and a 1-cm incision is used to retrieve the proximal end. Fulguration of the proximal (leg) side of the nerve is also required. The graft is placed in cooled saline. The skin is closed, and compression stockings ensure decreased hematoma formation (Kim and Seo, 2001). The average length of nerve needed per side is 5 to 6.5 cm; however, 40-cm segments can be isolated for bilateral procedures with minimal sensory deficit (Kim and Seo, 2001). The nerve graft is reversed, and the distal nerve is attached to the proximal cavernous nerve endings under magnification; similarly, the proximal nerve end is attached to the distal cavernous nerve endings. The nerve endings can be identified at the time of resection and marked with a stitch through the use of the CaverMap nerve

stimulator (Canto et al, 2001). The nerves are attached to the nerve endings with 7-0 polypropylene sutures secured with microclips. After the procedure, suction drains are placed and directed away from the graft site.

Many questions remain with respect to the need for nerve grafting after wide excision of the NVB after RRP (Walsh, 2001). Davis and colleagues (2009) reported a large series of patients undergoing unilateral nerve-sparing procedures with randomization to sural nerve grafting or standard erectile dysfunction therapy. At 2 years, no difference in potency was noted in the two groups (71% in nerve graft group and 67% in the standard group). Bilateral nerve grafting has resulted in a 5-year cumulative recovery of erectile function permitting penetration of 34% and the rate of consistent penetration of 11% (Secin et al, 2007). The young age, excellent baseline erectile function, and motivation to preserve erectile function in the cohort may explain why erectile function was preserved in a very small subset of cases undergoing the bilateral nerve grafts. Thus, although the techniques of nerve grafting are safe and feasible, the overall benefits appear limited. We do not perform nerve-grafting surgery.

SALVAGE RADICAL PROSTATECTOMY

The goal of primary external-beam radiation therapy (intensity-modified or three-dimensional conformal) or primary brachytherapy in the treatment of clinically localized prostate cancer is to eradicate all of the tumor. Failure to achieve this goal leads to local progression, distant metastasis, and potentially death. The recognition of local recurrence after definitive radiation therapy is complex (American Society of Therapeutic Radiology and Oncology criteria, PSA nadir, PSA bump), yet all would agree that it portends a poor outcome with few options for salvage. This poor prognosis led to development of several options to salvage cure: cryosurgery (see Chapter 105), watchful waiting (see Chapter 108), androgen deprivation (see Chapter 109), and salvage prostatectomy. **Salvage radical prostatectomy has been used successfully to eradicate locally recurrent cancer after definitive radiotherapy, but complications are common and the effects on overall survival uncertain** (Rogers et al, 1995; Cheng et al, 1998; Garzotto and Wajzman, 1998; Gheiler et al, 1998; Tefilli et al, 1998a, 1998b; reviewed by Chen and Wood, 2003; Stephenson et al, 2004; Ward et al, 2005; Paparel et al, 2009). From the literature, the following generalizations can be made:

- The procedure (salvage prostatectomy) is reserved for patients with excellent health and with a life expectancy of more than 15 years.
- Patients must have no evidence of metastatic disease.
- Salvage surgery should be offered only to men who at initial presentation had unequivocally clinically localized prostate cancer.
- Prostate biopsy, histologic grade, clinical examination findings, and serum PSA levels must continue to suggest localized disease.

In summary, candidates for salvage surgery should be unrecognizable from the candidates we would choose for initial therapy with RRP and be highly motivated individuals who understand and accept the potentially higher morbidity associated with salvage surgery.

A single institution review of a salvage prostatectomy experience by Stephenson and colleagues (2004) recounted a series of nearly 100 men treated between 1984 and 2003 with either external-beam ($N = 58$) or interstitial ($N = 42$) radiotherapy. The authors saw a decrease in complication rates (overall from 33% to 13%, rectal injuries from 15% to 2%). They also reported urinary continence rates of 39% totally dry and 86% with one or fewer pad per day. Nearly 20% required an artificial sphincter. The 5-year actuarial recovery of potency rate for this group was 16% (Masterson et al, 2005). Another recent report recounted a 30-year experience with salvage retropubic prostatectomy and cystoprostatectomy for radioresistant adenocarcinoma of the prostate (Ward et al, 2005). From

1967 to 2003, they found sufficient data to comment on 199 men; 138 were treated with retropubic prostatectomy and 61 with cystoprostatectomy. Average follow-up was 7 years. Rectal injury occurred in 5% of radical retropubic prostatectomies and 10% of cystoprostatectomies. Incontinence was “zero pads” in 43% of the more contemporary cohort. Cancer-specific survival was 65% at 10 years.

Data on oncologic outcomes after salvage radical prostatectomy are limited. Eastham and colleagues report excellent local control and a 45% 5-year recurrence in patients with presurgical biopsies demonstrating a Gleason score of less than 8 (Paparel et al, 2009). However, the overall effect of salvage prostatectomy on prostate cancer-specific mortality remains unclear (Paparel et al, 2009).

Chade et al (2011) reported a systematic review based on 40 publications in the English literature between January 1980 and June 2011. Oncologic, complications and functional outcomes were compared using 1993 as a cut point to examine trends related to earlier versus later publications. The majority of cases were performed after 1993. Positive surgical margins in the earlier versus later publications ranged between 43% and 70% and 0 and 36%, respectively. Pathologic organ-confined disease in the earlier versus later publications ranged between 22% and 53% and 44% to 73%, respectively, suggesting that the decrease in positive margin rates is in part related to lower volume disease. The risk for rectal injury, anastomotic stricture, and Clavien 3 to 5 complications ranged between 0 and 19%, 0 and 41%, and 0 to 33%, respectively. Preservation of potency outcomes is limited to the later publications and ranged between 0 and 28%. Urinary continence rates in the earlier versus later publications ranged between 46 and 90%, and 0 and 83%, respectively. The 5- and 10-year biochemical free survival ranged between 47% and 82% and 28% and 53%, respectively. Complications and functional outcomes were better in the later series, suggesting that improved surgical technique may contribute to better oncologic outcomes. The tremendous range of outcomes and salvage radical prostatectomy is likely explained by selection bias, surgical experience, and methodology for assessing quality of the outcomes. Because of the extreme range of all reported outcomes, it is difficult to appropriately counsel potential candidates regarding risks and benefits. Because of the significant risks for complications even among highly experienced surgeons, candidates should be carefully selected for the procedure.

The surgical technique for salvage prostatectomy does not differ from that of classic radical prostatectomy. Radiation effects (vasculitis, ischemia, and fibrosis) can make the surgical dissection technically challenging (Chen and Wood, 2003). Special care should be taken in separating the apical region of the prostate, wide dissection of the NVBs, and dissection of Denonvilliers fascia near the base of the prostate because these regions represent the most common sites for rectal injury.

SUMMARY OF RADICAL RETROPUBIC PROSTATECTOMY

A number of advances have been made in the diagnosis and treatment of localized prostate cancer. Today, more men are diagnosed with curable disease at a younger age. Men are also living longer; a man 65 to 70 years old has a 50% chance of living for another 15 years. Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it. These are also the patients who will have the best quality of life postoperatively (Walsh, 2000).

Over the last decade there has been increasing adoption of robotic-assisted laparoscopic radical prostatectomy. Some experts claim that the open approach is of only historical interest because of superior outcomes after the robotic approach. Comparative effectiveness studies suggest that the robotic approach may compromise surgical margins (Williams et al, 2010), achieve inferior continence and equivalent potency (Barry et al, 2012), and yield higher dissatisfaction rates (Schroek et al, 2008) while greatly increasing cost

KEY POINTS: ANATOMIC RADICAL RETROPUBIC PROSTATECTOMY

- There is no better way to cure cancer that is confined to the prostate than total surgical removal.
- The three goals of the surgeon, in order of importance, are cancer control, preservation of urinary control, and preservation of sexual function.
- Surgery is deferred for 6 to 8 weeks after needle biopsy of the prostate and 12 weeks after transurethral resection of the prostate.
- A fiberoptic headlight and 2.5- to 4.5-power loupes are most useful because much of the procedure is performed beneath the pubis in an area where visualization can be difficult. Magnification can enable the surgeon to exert less traction on the NVBs and more easily identify the correct plane of dissection.
- Regional anesthesia is associated with less blood loss and a lower frequency of pulmonary emboli.
- If the patient has a well-differentiated to moderately well-differentiated tumor (Gleason grade < 8) and the lymph nodes are normal to palpation, frozen-section analysis is not performed.
- With the recent recognition that branches of the nerves innervating the striated sphincter and cavernous bodies may travel more anteriorly at the apex, an alternative technique involving high anterior release of the NVBs at the apex before division of the dorsal vein is described. This technique is associated with earlier recovery of sexual function.
- Today, in most men who are candidates for surgery, it is safe to preserve both NVBs and rarely necessary to excise both of them, thus making cavernous nerve replacement or transplantation unnecessary in most cases.
- The tactile sensation provided by open surgery is very important. If induration is palpable in the lateral pelvic fascia, the bundle should be excised. In gently releasing the bundle with a right-angled clamp, if the bundle is fixed to the prostate, it should not be preserved. With the laparoscopic technique, tactile sensation is muted; with the robotic-assisted technique, it is absent.
- Patients requiring acute transfusions for hypotension after radical prostatectomy should be explored to evacuate the pelvic hematoma in an effort to decrease the likelihood of bladder neck contracture and incontinence.
- Thrombophlebitis with pulmonary embolism is the major cause of mortality after radical prostatectomy. Measures to prevent this complication include careful positioning on the operating room table to avoid compression of the veins in the lower extremity, the use of intermittent compression devices, and early ambulation.
- We concluded that complete excision of the seminal vesicle during radical prostatectomy is essential for cancer control.
- Open radical prostatectomy is an ideal form of treatment for patients who can be cured and who will live long enough to benefit from it.

with comparable pain and length of hospital stay (Lepor, 2009). The primary advantage of the robotic approach is less blood loss. Even proponents of the robotic approach concede after 10 years there is no meaningful advantage of the robotic approach (Lavery et al, 2012). Despite public demand, the authors of this chapter continue to perform the open approach.

RADICAL PERINEAL PROSTATECTOMY

This section is included in honor and the memory of Marty Resnick, MD. This slightly modified version of his chapter in *Campbell-Walsh Urology*, 9th edition reflects his career efforts in the field of urology and his expertise in performance of the RPP.

Hugh Hampton Young described the first RPP for treatment of cancer in 1905. In 1939, Belt and colleagues modified the procedure, and until the description of the radical retropubic approach by Walsh, this approach represented the principal method for treatment of patients with localized prostate malignant disease. Furthermore, Walsh improved on the retropubic technique, demonstrating functional anatomic relationships that reduced intraoperative blood loss and improved outcomes of impotence and urinary continence (Reiner and Walsh, 1979; Walsh and Donker, 1982; Walsh et al, 1983).

Surgical and anatomic techniques of the retropubic prostatectomy were applied to the perineal approach, resulting in potency comparable with that of the early RRP results (Weiss et al, 1985; Weldon, 1988; Weldon and Tavel, 1988). In addition, the perineal approach offers visualization of the urethral dissection and anastomosis, resulting in excellent urinary continence similar to the results achieved through the laparoscopic approach. Finally, RPP demonstrates the proved long-term cancer control of RRP with low morbidity and rapid convalescence (Sullivan et al, 2000; Guillonnet al, 2002; Harris, 2003; Lotan et al, 2004; Silverstein et al, 2004).

Selection of Patients

Like the RRP, RPP is offered to patients with a life expectancy of more than 10 years who demonstrate a high likelihood of organ-confined disease. A nerve-sparing approach is accomplished for most of these patients, and the decision to excise a NVB is usually made intraoperatively on the basis of the adherence of the NVB to the prostate or preoperatively on the basis of the biopsy report or results of the digital rectal examination. A pre-RPP laparoscopic pelvic lymphadenectomy is deemed unnecessary if the biopsy Gleason score is below 7 and the serum PSA level is less than 10 ng/mL (low- to moderate-risk disease).
